14 Abstract

15 Leaf area index (LAI) is an important quantity in the study of forest ecosystems, but  
16 field measurements of LAI often contain errors because of the vertical complexity of  
17 the forest canopy. In this study, we established a practical method for field  
18 measurement of LAI in the canopy of a deciduous broadleaved forest by accounting  
19 for its vertical complexity. First, we produced a semi-empirical model for the  
20 vertical integration of leaf dry mass per unit leaf area. We also quantified the  
21 litterfall for each tree species. These data enabled us to estimate the LAI of each  
22 species in autumn. By periodic *in situ* monitoring of some fixed sample shoots  
23 throughout the growing season, we were able to estimate the seasonality of leaf  
24 area (as a proportion of the annual maximum value at each point in time) of each  
25 species. By using this seasonality to extrapolate LAI values as a proportion of the  
26 LAI data in the leaf-fall season, we were able to estimate LAI throughout the year.  
27 We applied this method in a cool-temperate deciduous forest in central Japan  
28 (Takayama) in 2006 and validated our results using two conventional methods of  
29 LAI measurement: the plant canopy analyzer (LAI-2000) and the Tracing Radiation  
30 and Architecture of Canopies (TRAC) approach. LAI estimated by TRAC was in good  
31 agreement with our results, but LAI estimated using the LAI-2000 was only half the  
32 value estimated using our method. The use of basal area data as a proxy for species-  
33 specific leaf areas may save labor and time. Our method will be useful for studying  
34 the dynamics and interactions of multiple species because it can estimate LAI and its  
35 seasonal changes for each species.

39 1. Introduction

40 The leaf area in a forest canopy is an important quantity in understanding many  
41 ecosystem processes and characteristics of the forest. For example, photosynthesis,  
42 transpiration, aerodynamic roughness, autotrophic respiration, and other important  
43 parameters can be represented by integrating the functions of individual leaves for  
44 each tree's total leaf area. This idea, originating from the proposition by Monsi and  
45 Saeki (1953; republished in 2005), has been verified in various ecosystems from  
46 various standpoints (e.g., Hirose, 2005) and has become the theoretical basis for  
47 studying the functional interactions between a forest and its environment (e.g.,  
48 Aber et al., 1996; de Pury and Farquhar, 1997; Watanabe et al., 2004; Walcroft et  
49 al., 2005). Most such studies have described leaf area using the leaf area index  
50 (LAI) parameter, which is defined as half of the total leaf area (i.e., the area for  
51 only one leaf surface) divided by the ground surface area beneath those leaves (e.g.,  
52 Chen and Black, 1992; Jonckheere et al., 2004). However, field measurements of  
53 LAI often contain errors because of the vertical complexity of a forest canopy's  
54 structure, such as the mixture of multiple species with different characteristics, the  
55 presence of stems and branches, variation among the leaves (e.g., in their size,  
56 angle, thickness), and temporal changes in these factors.

57 Indirect optical methods for the field measurement of LAI, such as the  
58 LAI-2000 Plant Canopy Analyzer (Li-Cor Inc., Lincoln, NE, USA; e.g., Norman and  
59 Campbell, 1989), the Tracing Radiation and Architecture of Canopies approach  
60 (TRAC, 3rd Wave Engineering, Nepean, Ontario, Canada; Chen and Cihlar, 1995;

61 Leblanc and Chen, 2001), hemispherical photography (e.g., Muraoka and Koizumi,  
62 2005) and light transmittance (e.g., Saigusa et al., 2002), assume a simple canopy  
63 architecture with little vertical complexity. Therefore, the accuracy of these methods  
64 is controversial (e.g., Jonckheere et al., 2004). In contrast, destructive sampling  
65 methods can directly provide the LAI value for each species (hereafter, the  
66 “component LAI”). However, it is difficult to monitor temporal changes in LAI with  
67 this method because we cannot always repeatedly destructively sample forest stands  
68 and because the method is prohibitively time-consuming. Allometric approaches  
69 (e.g., Macfarlane et al., 2007) can replace destructive sampling, but it remains  
70 difficult to monitor seasonal changes using this approach.

71         For a deciduous forest, it is possible to overcome some of these problems  
72 using litter traps (e.g., Jonckheere et al., 2004): If leaf expansion and leaf fall do  
73 not take place simultaneously, we can estimate the biomass of leaves in the canopy  
74 during the leaf-fall season by collecting leaf litter in litter traps on the forest floor.  
75 We can then estimate the component LAI by sorting the leaf litter by species (e.g.,  
76 Tateno et al., 2005). However, this method provides little information about LAI  
77 during the leaf-expansion season. Moreover, to convert the biomass value into leaf  
78 area values, we must calculate either the leaf dry mass per unit of leaf area (LMA)  
79 or the specific leaf area (SLA), which is the reciprocal of LMA. In order to estimate  
80 LMA or SLA, we must account for their vertical variability (e.g., Eriksson et al.,  
81 2005).

82         In the present study, we aimed to develop a practical method for field

83 measurement of LAI in the canopy of a deciduous broadleaved forest that accounts  
84 for the canopy's vertical complexity and for seasonal changes. Our method  
85 combines three components. First, we propose a semi-empirical model for the  
86 vertical integration of LMA within a canopy. Second, using this model and litter-  
87 trap observations, we estimate the component LAI during the leaf-fall season. Third,  
88 by periodically obtaining *in situ* observations of sample shoots, we can estimate the  
89 pattern of relative change (hereafter, "seasonality") of the component LAIs. By  
90 scaling the seasonality of the component LAIs so that they are continuously  
91 connected to the component LAI in the leaf-fall season, we can extend our  
92 estimation of component LAI into the leaf-expansion season. By adding the  
93 component LAI of all species, we can then obtain LAI for the entire canopy from the  
94 initial leaf expansion to leaf fall. We implemented this method in a Japanese cool-  
95 temperate deciduous broadleaved forest. Using this result as a reference value, we  
96 validated it against two conventional indirect optical methods (LAI-2000 and  
97 TRAC).

98

## 99 2. Materials and methods

### 100 2-1. Study site

101 The study site is a cool-temperate deciduous broadleaved forest near Takayama, in  
102 central Japan (137.4231°N, 36.1462°E, 1420 m a.s.l.; Fig. 1). The annual mean air  
103 temperature and the mean annual rainfall from 1980 to 2002 were 7.2°C and 2275  
104 mm, respectively. The site is covered by a snowpack that ranges from 100 to 180 cm

105 in depth from December until April (Mo et al., 2005). A tree census has been  
106 carried out every year since 1999 (Ohtsuka et al., 2005). The fluxes of CO<sub>2</sub>, water  
107 vapor, and sensible heat have been observed at a flux tower since 1993 (Yamamoto  
108 et al. 1999; Saigusa et al. 2002, 2005; Fig. 1). Leaf physiology (photosynthesis and  
109 respiration) of some dominant species has been observed using a canopy-access  
110 tower that is 18 m tall (Muraoka and Koizumi, 2005; Fig. 1). Some ecophysiological  
111 models have been developed and tested for this site (Higuchi et al., 2005; Ito et al.,  
112 2005, 2006).

113 (Insert Fig. 1 here)

114 The species composition of the canopy trees at the study site is as follows:  
115 The dominant tree group consists of *Quercus crispula* and *Betula ermanii*, with some  
116 *Fagus crenata*, *Betula platyphylla*, and *Magnolia obovata*. The co-dominant trees  
117 include *Acer distylum*, *Acer rufinerve*, *Acanthopanax sciadophylloides*, *Tilia japonica*,  
118 *Sorbus alnifolia*, and *Kalopanax pictus*. The suppressed trees include *Hydrangea*  
119 *paniculata* and *Viburnum furcatum*. Under the suppressed trees, the forest floor is  
120 covered by an understory of evergreen dwarf bamboo (*Sasa senanensis*) with a  
121 height of 1.0 to 1.5 m. The height of the dominant forest canopy ranges from 13 to  
122 20 m.

123 Most observations were carried out from April to November 2006. For the  
124 study area, the leaf-expansion season is the period from April to mid-August, and  
125 the leaf-fall season is the period from late August to November.

126

127 2-2. A model for the vertical integration of LMA within a canopy  
128 Even within the same species or the same individual, leaf characteristics vary within  
129 the canopy, mainly due to variations in light conditions. For the sake of simplicity,  
130 we have considered only two extreme cases of this variation as a function of height,  
131 namely the leaf at the top position on the stem (hereafter, the “top leaf”) and a leaf  
132 at the lowest position (hereafter, called “bottom leaf”). Using these two extremes,  
133 we can approximate the entire canopy as a mixture of these two leaf types.

134 In our model, we define the  $z$ -axis as extending vertically downward from  
135 the canopy surface ( $z = 0$ ). At the forest floor,  $z = Z$ . We denote total LAI as  $L$ . We  
136 denote the cumulative leaf area over a unit area of ground from  $z = 0$  to  $z$  as  $l(z)$ .  
137 Obviously,  $l(0) = 0$  and  $l(Z) = L$ . Let  $m = \text{LMA}$ , which depends on  $z$ .

138 To begin our analysis, let us consider a canopy composed of a single species.  
139 For a thin layer between  $z$  and  $z + dz$  within the canopy, the leaf area in this layer  
140 ( $dL$ ) is  $dL = L(z + dz) - L(z)$ . The leaf dry mass ( $dM$ ) in this layer is represented as:  
141  $dM = m dL$ . Therefore, the total dry mass ( $M$ ) of the entire canopy per unit of  
142 ground area is:

143

$$144 \quad M = \int dM = \int_0^L m dl . \quad (1)$$

145

146 Niinemets and Tenhunen (1997) proposed the following relationship based on field  
147 study data and a semi-empirical model of a deciduous broadleaved forest:

148

149 
$$m = a \exp(-bL), \tag{2}$$

150

151 where  $a$  and  $b$  are constants that depend on the species and site. Dufrêne et al.  
152 (2005) adopted this function in their numerical model. We have assumed that this  
153 formula is generally valid for deciduous broadleaved forests.

154 We denote the LMA values of the top leaf and the bottom leaf as  $m_0$  and  $m_1$ ,  
155 respectively. From equation (2), it is obvious that  $m_0 = m(0) = a$  and  $m_1 = m(Z) =$   
156  $m_0 \exp(-bL)$ . Therefore,

157

158 
$$a = m_0 \quad \text{and} \quad b = \frac{1}{L} \ln \frac{m_0}{m_1}. \tag{3}$$

159

160 By substituting equations (2) and (3) into equation (1), we get:

161

162 
$$M = L \frac{m_0 - m_1}{\ln m_0 - \ln m_1}. \tag{4}$$

163

164 From this equation, the average LMA ( $m_a$ ) of the entire canopy can be defined as  
165 the total dry leaf mass divided by the total leaf area:

166

167 
$$m_a = \frac{M}{L} = \frac{m_2 - m_3}{\ln m_2 - \ln m_3} . \quad (5)$$

168

169 Now, let us extend this formula to a complex canopy with multiple species.

170 First, let us consider a layer occupied by a single species between  $z = z_2$  and  $z = z_3$

171 in the canopy. We describe  $l(z_2)$  as  $l_2$  and  $l(z_3)$  as  $l_3$ . We can describe LMA at  $z_2$  and

172  $z_3$  as  $m_2$  and  $m_3$ , respectively. We assume that equation (2) is valid for the layer

173 occupied by the single species within the complex canopy. From this assumption,  $m_2$

174  $= a \exp(-bl_2)$  and  $m_3 = a \exp(-bl_3)$ . Therefore,

175 
$$b = \frac{1}{L_{23}} \ln \frac{m_2}{m_3} . \quad (6)$$

176 where,  $L_{23} = l_3 - l_2$ . The leaf dry mass in this layer ( $M_{23}$ ) can be calculated in the same

177 way as equation (4):

178 
$$M_{23} = L_{23} \frac{m_2 - m_3}{\ln m_2 - \ln m_3} \quad (7)$$

179

180 If we define the average LMA in this layer ( $m_{a23}$ ) as  $M_{23} / L_{23}$ ,

181

182 
$$m_{a\Box} = \frac{M_{\Box}}{L_{\Box}} = \frac{m_{\Box} - m_{\Box}}{\ln m_{\Box} - \ln m_{\Box}} , \quad (8)$$

183

184 which is similar to equation (5).

185 Now let us consider how the canopy (or a layer) of a single species can be  
186 represented as a mixture of top and bottom leaves. Because the LAI of the canopy is  
187 the sum of the LAI of the two types of leaves,  $L = L_0 + L_1$ . Then, the total leaf dry  
188 mass ( $M$ ) can be represented as  $M = m_0L_0 + m_1L_1$ . This must be equal to equation  
189 (4). Therefore,

190

$$191 \quad m_0L_0 + m_1L_1 = L \frac{m_0 - m_1}{\ln m_0 - \ln m_1} . \quad (9)$$

192

193 We can simplify this equation to eliminate  $L_1$  by using the relationship  $L = L_0 + L_1$ ,  
194 producing the following formula:

195

$$196 \quad \frac{L_0}{L} = \frac{1}{\ln m_0 - \ln m_1} - \frac{m_1}{m_0 - m_1} . \quad (10)$$

197

198 This tells us about the fraction of top leaves in the canopy. We can estimate the  
199 fraction of the bottom leaves by subtracting this result from 1.

200 In a field study in southern Swedish forest stands, Eriksson et al. (2005) used  
201 equal proportions of the top and bottom leaves when estimating average tree SLA.

202 In that case, the equation corresponding to equation (8) is  $1 / m_{ae} = [(1 / m_0) +$   
203  $(1 / m_1)] / 2$ , or equivalently:

204

205 
$$m_{ae} = \frac{2 m_0 m_1}{m_0 + m_1} \quad (11)$$

206

207 where  $m_{ae}$  is the average LMA under the assumption of Eriksson et al. (2005).

208

### 209 2-3. Observation of LMA

210 In order to determine the LMA of each species, we sampled the top and bottom  
211 leaves of each dominant species in August, September, and October in 2006 and  
212 2007. We measured LMA of each leaf as follows: First, we measured the area of  
213 each leaf by scanning the leaf with an ES-7000H image scanner (SEIKO EPSON Co.,  
214 Japan, 300 dpi resolution). We calculated the leaf's area by counting the number of  
215 leaf pixels and multiplying this total by the pixel size using the LIA-32 image-  
216 analysis software (<http://www.agr.nagoya-u.ac.jp/%7Eshinkan/LIA32>). Most  
217 leaves were flat. The non-flat leaves (wrinkled or rolled) were flattened by the lid of  
218 the image scanner. After the area measurement, we dried the leaf samples in an  
219 oven at 80°C for more than 48 h. We then measured the dry mass of each sample.  
220 By dividing the dry mass by the leaf area, we obtained LMA for each sample. Then,  
221 using equation (8), we obtained the average LMA for each species. Strictly  
222 speaking, LMA can change along with growth and aging of the leaves. However, we  
223 neglected this change because the change was estimated to be insignificant so far as  
224 we limit it in the late summer and autumn.

225

226 2-4. Litter-trap observations

227 At the study site, we installed 14 litter traps within a 1-ha permanent sample plot  
228 that is being used for ecological surveys (Fig. 1). Each trap had a square aperture of  
229 1 m<sup>2</sup>. Their locations were chosen so that they covered a wide range of site  
230 topographic conditions (ridge, slope, and valley) and tree species. In particular, we  
231 avoided placing multiple traps under the crown of a single tree. The litter (leaves,  
232 branches, seeds, etc.) caught in the traps were recovered on August 25, September  
233 17, September 30, October 9, October 22, November 4, and November 18. During  
234 each litter collection, we sorted the litter in each trap into the leaves of each species.  
235 Because it was difficult to distinguish between the leaves of *B. ermanii* and *B.*  
236 *platyphylla*, we treated them as a single *Betula* category. The tree census data for  
237 this site (Ohtsuka et al., 2005) suggest that *B. ermanii* occupied 63% of the total  
238 basal area in the *Betula* category. We discarded the leaves of evergreen trees such as  
239 *Pinus parviflora* because their amount was small. In fact, the evergreen trees  
240 occupied only 2.8% of the site's basal area and only 1.0% of the individuals that  
241 formed the entire canopy (Ohtsuka et al., 2005). After oven-drying the leaves at  
242 approximately 70°C for longer than 48 h, we measured the mass of the dried leaves.  
243 By dividing this mass by the average LMA, we estimated the area of the fallen leaves  
244 of each species at the time of sampling. By adding the area of the fallen leaves from  
245 August 25 to November 18, we obtained a total LAI, and were able to estimate the  
246 component LAI at each point between these dates for the leaf-fall season.

247

248 2-5. Leaf seasonality observations

249 We carried out leaf seasonality observations by means of periodic *in situ* observation  
250 of sample shoots. We selected 20 shoots of 18 individuals of 8 species for these  
251 samples, all of which we could directly access from the canopy access tower or the  
252 forest floor (Table 1). The selection of the 8 species was based on their relative rank  
253 in the total tree biomass for the site (Ohtsuka et al., 2005). The selection of the 20  
254 sample shoots was based on ease of access and the goal of measuring shoots at a  
255 variety of positions.

256 (Insert Table 1 here)

257 On May 12, May 22, June 2, June 16, June 29, July 30, August 18,  
258 September 17, September 30, October 9, October 22, and November 5, we obtained  
259 the following observations for each sample shoot: the number of all leaves on the  
260 shoot and the size (length and width) of about 20 randomly selected leaves on each  
261 shoot. By approximating the shape of the leaves as an ellipse and assuming that the  
262 measured length and width represented the longest and shortest axes of the ellipse,  
263 respectively, we estimated the area of each leaf. Summation of these leaf areas gave  
264 us an estimate of total leaf area on the shoot at that point in time. Thus, we  
265 obtained a time series for the seasonal changes in total leaf area on each shoot. By  
266 normalizing these data so that the seasonal peak value became 1.0, we obtained the  
267 seasonality of the leaf area (i.e., the proportion of the maximum value at each point  
268 in time) for each shoot. By averaging these results within each species, we obtained  
269 the seasonality of the overall leaf area of each species. For *Betula* and *Quercus*, we

270 averaged the seasonality at the top position and at the bottom position separately,  
271 and then averaged the result using a fractional weight derived from equation (10).

272         These seasonality data were assumed to represent the seasonality of the  
273 component LAI. The average seasonality of *A. distylum* and *A. rufinerve* was  
274 assumed to represent the seasonality of the other codominant tree species. In the  
275 same way, the average seasonality of *H. paniculata* and *V. furcatum* was assumed to  
276 represent the seasonality of other suppressed tree species.

277

## 278 2-6. Development of seasonal LAI

279 We multiplied the seasonality of the component LAI so that it continuously  
280 connected to the component LAI for the leaf-fall season estimated by the litter-traps.  
281 This allowed us to extrapolate our results to obtain estimates of component LAI  
282 throughout the leaf-expansion season. By combining these results, we were able to  
283 estimate component LAI throughout the growing season. We also obtained the total  
284 LAI of the entire canopy (excluding *Sasa*) by adding the component LAI values for  
285 all the species.

286         LAI of *Sasa* on the forest floor in this site was estimated in April 1999 at 119  
287 sampling points (Sakai et al., 2002), and the result was a mean of 1.71, with a  
288 standard deviation of 0.933. Assuming statistical independence among the 119  
289 samples, the standard error of the mean was 0.09. Leaf biomass of *Sasa* at this site  
290 was mostly stable for all seasons in 1993 and 1994 (Nishimura et al., 2004). Based  
291 on these two results, we assumed a constant LAI of 1.71 for *Sasa*, with a standard

292 error of 0.09.

293

## 294 2-7. Observations of LAI using indirect optical methods

295 We used LAI-2000 to measure LAI on May 14, June 2, June 30, July 31, September  
296 8, and October 23. We used two LAI-2000 instruments simultaneously: one to  
297 measure incoming light from the sky above the canopy, and the other to measure  
298 transmitted light at ground level. The LAI-2000 at the top of the canopy access  
299 tower was operated in automatic mode, with measurements recorded at 15-s  
300 intervals. The LAI-2000 at ground level was moved around the site by a researcher  
301 to obtain measurements above the *Sasa* canopy (approximately 1.5 m above the  
302 ground), taking five measurements within 10 s each time at each location (mostly  
303 at or near the litter traps). LAI-2000 measurements were also obtained below the  
304 *Sasa* canopy (approximately 0.1 m above the ground) on May 14 in order to  
305 estimate the LAI of *Sasa*. We analyzed the data from the two LAI-2000s using the Li-  
306 Cor FV2000 software (version 1.06), with all the initial parameters and conditions  
307 left at the software's default values.

308 We performed TRAC measurements on June 3 and June 29 along the two  
309 100-m transects shown in Figure 1. During each measurement, we also monitored  
310 the photosynthetic photon flux density (PPFD) every 5 s with a quantum sensor  
311 (IKS-27, Koito Industries, LTD., Yokohama, Japan) at the top of the canopy access  
312 tower. We analyzed the TRAC data using the TRACWIN software (version 3.9.1).  
313 We tested four groups of parameter settings for each TRAC measurement using two

314 values for “PPFD above” (the maximum and minimum PPFD values measured at the  
315 canopy tower) and two values for “mean element width” (the upper and lower  
316 limits of the range within one standard error of the mean leaf diameter estimated  
317 using the litter-trap and leaf-seasonality observations).

318 In general, these indirect methods inevitably observe not only leaves but also  
319 stems and branches within their field of view. Therefore, their results are not true  
320 LAI values, but rather PAI (plant area index) values, which equal the sum of LAI  
321 and SAI (stem area index; the total stem and branch area per unit of ground surface  
322 area). We assumed SAI to be invariant and equal to the PAI value observed with the  
323 LAI-2000 on May 14, when all the deciduous trees had no leaves. By subtracting  
324 this SAI value from the PAI values taken by the LAI-2000 and TRAC, we estimated  
325 LAI. Because we obtained these indirect observations above *Sasa* on the forest floor  
326 in most cases, these PAI and LAI values excluded the values for *Sasa*.

327

### 328 3. Results

#### 329 3-1. LMA

330 We obtained LMA values for the study species that ranged from 25 to 92 g m<sup>-2</sup>  
331 (Table 2). The standard error of each LMA value was less than 6% of the mean. In  
332 all species except for *V. furcatum*, the LMA of the top leaves was 1.5 to 2.1 times  
333 that of the bottom leaves; for *V. furcatum*, there was little difference between the  
334 two leaf types. The average LMA derived using equation (8) ranged from 32 to 76 g  
335 m<sup>-2</sup>.

336 (Insert Table 2 here)

337 We tested equation (11) with our data and found that the resulting average  
338 LMA was 74.4 g m<sup>-2</sup> for *B. ermanii*, 68.5 g m<sup>-2</sup> for *Q. crispula*, and 30.7 g m<sup>-2</sup> for *H.*  
339 *paniculata*. These values were smaller than the average LMA calculated using  
340 equation (8), but the difference was less than the standard error.

341

### 342 3-2. Litter-trap observations

343 As of late summer (August 25), the canopy LAI (excluding *Sasa*) equaled 5.0, of  
344 which 70% was accounted for by the dominant group, 16% by the codominant  
345 group, and 14% by the suppressed group. The standard error of the total LAI was  
346 0.3. This error was attributable to both the limited number of the litter traps (14)  
347 and the error associated with LMA.

348

### 349 3-3. Leaf-seasonality observations

350 All the species showed clear seasonality of leaf number, single-leaf size, and leaf  
351 area per shoot (Fig. 2). As seen in the changing number of leaves (left column of  
352 Fig. 2), most species except *B. ermanii* had a single leaf flush (a rapid emergence of  
353 leaves) in May. In contrast, *B. ermanii* showed two leaf flushes: the first one in late  
354 May and the second in late June. Because of the small new leaves produced during  
355 the second flush, the mean single-leaf area of *B. ermanii* decreased in late June. The  
356 new leaves in the second flush never grew as large as the leaves in the first flush,  
357 thus the mean single-leaf area after June did not recover to the maximum level

358 attained in May. For some species (*Q. crispula* and *F. crenata* in particular), the  
359 single-leaf area decreased slightly from the leaf flush until August, probably because  
360 of herbivory by insects.

361 (Insert Fig. 2 here)

362         After summer, the single-leaf area of some species showed irregular changes.  
363 For example, the single leaf area of *M. obovata* decreased temporarily in early  
364 October and then recovered. This irregularity could occur in the following manner:  
365 when large leaves on the shoot fell, the average single-leaf area decreased  
366 temporarily, but thereafter, when small leaves fell, the average single-leaf area  
367 recovered. Conversely, the single-leaf area of *F. crenata* temporarily increased in  
368 October. Such irregularity is partly attributable to statistical errors resulting from  
369 the small sample size.

370         The seasonality of leaf area per shoot during the leaf-fall season differed even  
371 within a species (particularly for *B. ermanii* and *H. paniculata*), so that the standard  
372 error of the leaf area was larger than that during the leaf-expansion season. Except  
373 for the leaf-fall period, the standard error of seasonality of leaf area per shoot was  
374 mostly less than 0.1. This magnitude of error suggests that the selection of 20  
375 sample shoots offers a valid method for representing the seasonality of the  
376 component LAI only during the leaf-expansion season.

377

378 3-4. LAI in all seasons

379 By combining the litter-trap data with the leaf seasonality data, we were able to

380 estimate the component LAI during all seasons (Fig. 3). *Betula* had the largest peak  
381 LAI, followed by *Q. crispula*.

382 (Insert Fig. 3 here)

383 The total LAI (Fig. 4) also showed clear seasonal changes with a maximum of  
384 7.0 on July 30. Throughout most of the study period, the dominant group  
385 accounted for the majority of the total LAI. However, *Sasa* accounted for the  
386 majority of LAI in May and November because most of the deciduous trees had no  
387 leaves on their branches at this time. The codominant group and the suppressed  
388 group also accounted for higher fractions than the dominant group in mid-May  
389 because their leaf flush happened earlier than that of all trees in the dominant  
390 group except for *F. crenata*.

391 (Insert Fig. 4 here)

392

393 3-5. LAI estimation using indirect optical methods

394 SAI was estimated to be 0.8 from the LAI-2000 observations on May 14. By  
395 subtracting this SAI value from PAI, we estimated LAI with the LAI-2000 and the  
396 TRAC approach (Fig. 5). The LAI-2000 gave obviously lower LAI values (by about  
397 half) than those provided by our method throughout the study. Moreover, the  
398 pattern of seasonal change was different: in July, the LAI-2000 showed a continuing  
399 increase of LAI (by as much as 20% of the annual peak), whereas our method  
400 showed little increase. In contrast, the TRAC LAI values were close to those  
401 provided by our method. The LAI of *Sasa* was estimated to be 1.55 (with a standard

402 error of 0.10,  $n = 21$ ) using the LAI-2000 observations on May 14, which was close  
403 to our assumption of 1.71.

404 (Insert Fig. 5 here)

405

#### 406 4. Discussion

##### 407 4-1. Reliability and utility of the proposed method

408 The average LMA of each species derived using equation (8) showed little difference  
409 from the average LMA calculated using equation (11). However, if  $L_0$  and  $L_1$  differ  
410 greatly, the choice of equation becomes more critical. In order to address this issue,  
411 we need further tests of the relationship between the cumulative leaf area and the  
412 LMA proposed by Niinemets and Tenhunen (1997). This would require  
413 stratification of the number of the fallen leaves (leaf litter) in each LMA category,  
414 something we could not do in the present study because it was difficult to measure  
415 the area of the fallen leaves, which were deformed and distorted as a result of  
416 drying between collection dates.

417 The eight species that we selected for the leaf-seasonality observations  
418 accounted for 84% of LAI (on August 25, excluding *Sasa*) estimated from the litter-  
419 trap data. This means that the seasonality of about 16% of total LAI was uncertain.  
420 Therefore, in order to attain more accurate assessments of the seasonality of LAI,  
421 we should obtain observations for more species (especially for *T. japonica*) that  
422 were ignored in the present study.

423 From a practical standpoint, our method offers the advantage that it can

424 work under any weather and light conditions. In contrast, the LAI-2000 and TRAC  
425 approaches require suitable weather and light conditions, which are not always  
426 available. However, our method is laborious in comparison to these alternatives. In  
427 particular, the process of sorting the leaf litter requires considerable time and a  
428 certain amount of expertise. If we could eliminate this part of the process, our  
429 method would become more convenient. To do so, it would be helpful to have a  
430 reliable proxy for the component LAI that is easier to measure in the field.

431 Figure 6 shows that the fraction of the component LAI (excluding evergreen  
432 trees and *Sasa*) of the major species in August corresponded well to the fraction of  
433 their total basal area estimated from a tree census study (Ohtsuka et al., 2005). This  
434 relationship is consistent with a study of the allometric relationship for 46 North  
435 American deciduous species, in which Niklas (1994) found that leaf area increased  
436 with the square of stem diameter (i.e., with increasing basal area). Based on this  
437 relationship, it may be possible to eliminate the process of sorting the leaf litter.

438 (Insert Figure 6 here)

439

#### 440 4-2. Validation of LMA used in previous studies

441 From the total leaf dry mass of  $315 \text{ g m}^{-2}$  and the total LAI (excluding *Sasa*) of 5.0  
442 on August 25, the LMA for the entire canopy (excluding *Sasa*) was estimated as  $63$   
443  $\text{g m}^{-2}$ . In comparison, a previous ecophysiological process model (Ito et al., 2005)  
444 reported LMA equal to  $67 \text{ g m}^{-2}$  (based on an SLA value of  $150 \text{ cm}^2 \text{ g}^{-1}$ ), which is  
445 slightly higher than our value. On the other hand, Ito et al. (2006) reported that

446 LMA equaled 93.1 g m<sup>-2</sup> for *Q. crispula* and 69.2 g m<sup>-2</sup> for *Betula* in another  
447 modeling study, and these values differed greatly from our estimates of 69.7 and  
448 76.3 g m<sup>-2</sup>, respectively (Table 2). We believe that this discrepancy is mostly  
449 attributable to the vertical scaling that we performed, which was not attempted in  
450 previous studies at this site.

451

#### 452 4-3. Comparison with indirect optical methods of LAI estimation

453 Obviously, it is impossible for every study to carry out such detailed measurements  
454 as those in the present study. Therefore, it is desirable to validate and improve the  
455 indirect optical methods because they are easier and quicker to carry out. In  
456 comparison with our method, the TRAC method provided comparable LAI values  
457 (although we did not validate this approach for the later parts of the growing  
458 season), but the LAI-2000 gave lower LAI values and a dissimilar pattern of  
459 seasonal change. One possible cause for this discrepancy is the clumping effect (e.g.,  
460 Leblanc and Chen, 2001), which is accounted for by the TRAC method but not by  
461 the LAI-2000 method. The clumping index must equal about 0.5 to explain the  
462 discrepancy between these two instruments. However, the actual clumping index  
463 estimated using the TRAC data ranged between 0.91 and 0.95. Therefore, the  
464 clumping index alone cannot explain the discrepancy.

465 Our results also suggest underestimation of LAI values derived by indirect  
466 methods in previous studies at this site. In 1997 and 1998, Saigusa et al. (2002)  
467 used transmittance of PPFD to estimate the annual peak PAI (excluding *Sasa*),

468 which ranged between 3 and 4. In 2003, using hemispherical photography,  
469 Muraoka and Koizumi (2005) estimated an annual peak PAI of 4.0 (excluding *Sasa*)  
470 at 14 locations at this site (mostly corresponding to the litter traps in the present  
471 study). If we assume that  $SAI = 0.8$ , then the annual peak LAI (excluding *Sasa*) in  
472 these two studies should be between 2.2 and 3.2, which is smaller than our estimate  
473 of 5.3 on July 30 for the annual peak LAI (excluding *Sasa*). However, the PAI values  
474 reported by Muraoka and Koizumi (2005) showed seasonal changes that were  
475 consistent with the pattern revealed using our proposed method.

476 To learn the reasons for the discrepancy among the methods, we will need to  
477 validate each step in the derivation of LAI in each method, which is the next step  
478 after the present study. Along with the leaf seasonality observations, we also  
479 observed the distribution of leaf angles and leaf transmittance of each tree species.  
480 These data, which we will present in a future paper, should provide more detailed  
481 evidence for the causes of errors in the indirect methods.

482

#### 483 4-4. Ecological implications

484 In general, the tree species in cool-temperate deciduous forests in Japan are  
485 categorized into “single leaf flush” types such as *Fagus* spp., *Quercus* spp., and *Acer*  
486 spp., and “indeterminate leaf production” types such as *Betula* spp. (Koike, 1988;  
487 Kikuzawa, 2005). Trees of the “single leaf flush” type have a leaf flush that occurs  
488 within a single short period in the early growing season, whereas trees of the  
489 “indeterminate leaf production” type have either a gradual leaf flush or several

490 consecutive leaf flushes. The former type has smaller LMA values than the latter  
491 type. All these characteristics are considered to be related to their adaptation  
492 strategy to maximize light acquisition and utilization. In this study, these  
493 characteristics were obvious (Table 2, Fig. 2, Fig. 3).

494         These characteristics were reflected in the seasonal changes in component  
495 LAI. For example, trees in the codominant group accounted for the majority of total  
496 LAI (excluding *Sasa*; Fig. 4) early in the growing season (May). This may relate to  
497 the favorable light conditions created by the slower leaf expansion of the dominant  
498 trees. Such favorable light conditions for the codominant group, which has been  
499 called the “seasonal gap” (Yamamoto, 2000), should depend on the species  
500 composition and ecophysiological characteristics of the dominant group. For  
501 example, if *Q. crispula* become the majority of the dominant group (currently *Betula*  
502 spp.), the earlier leaf-flush and later leaf-fall of *Q. crispula* will create a shorter  
503 “seasonal gap,” resulting in a more severe environment for the trees below this  
504 canopy. Such an influence could be demonstrated using a numerical model that  
505 describes the regeneration process as well as the seasonality of leaf area for each  
506 species. This modeling would give insights into the consequences of interactions  
507 between forest canopy structure, the resulting light environment, and regeneration  
508 processes (Percy, 1990; Kupperts, 1994), all of which are affected by the vertical  
509 complexity of the canopy. Our method can contribute to such quantitative studies  
510 by providing fundamental data that can be used to explain the seasonal changes in  
511 the component LAI.

512

## 513 5. Conclusions

514 We were able to estimate the total LAI of a Japanese deciduous broadleaved forest  
515 by accounting for the vertical complexity of the canopy and its seasonal changes.

516 This method can provide not only total canopy LAI but also the component LAI (i.e.,  
517 LAI values for each species) and its seasonal changes. In this method, it may be  
518 possible to eliminate the most laborious step (sorting of leaf litter by species) if the  
519 basal area of each species is available. Our method provided considerably higher  
520 LAI values than those estimated using the LAI-2000 approach, but comparable  
521 values to those provided by the TRAC approach.

522

## 523 Acknowledgments

524 Hiroshi KOIZUMI, Tsuyoshi AKIYAMA, Kenji KURUMADO, and Yasunori  
525 MIYAMOTO of Gifu University provided us with critical support during the field  
526 observations. Masayasu MAKI of Kyoto University, Toru SAKAI and Takehiko  
527 YAMAJI of the University of Tokyo, Toshiharu KOJIMA of Gifu University, and  
528 Takafumi IKEDA, Kentaro TAKAYASU, Takeshi MOTOHKA, and Bunkei  
529 MATSUSHITA of the University of Tsukuba helped with our processing of the leaf  
530 samples. This study was supported by the Global Environmental Research Fund  
531 (S-1: Integrated Study for Terrestrial Carbon Management of Asia in the 21st  
532 Century Based on Scientific Advancement) of the Ministry of Environment of Japan  
533 and a grant from the Ministry of Education, Culture, Sports, Science and

534 Technology, Japan (Satellite Ecology, the 21st Century COE Program at Gifu  
535 University).

639 Table 1. Sample shoots for the *in-situ* leaf-seasonality observation

640 Table 2. Leaf mass per unit leaf area (LMA;  $\text{gm}^{-2}$ ) of the major tree species

641 Fig. 1. Top: Location of the Takayama (TKY) site in Japan. Bottom: Arrangement of  
642 the litter traps and the Tracing Radiation and Architecture of Canopies (TRAC)  
643 measurement transects at the Takayama Site. Each litter trap is identified with a  
644 label made of a symbol “L” and a two-digit number from L03 to L17 (L01, L02, and  
645 L06 do not exist).

646 Fig. 2. Seasonality of leaf characteristics for the tree species. For *B. ermanii* and *Q.*  
647 *crispula*, the top and bottom shoots in the canopy are presented separately. Error  
648 bars represent the standard error. Each time series for the data was normalized  
649 using the annual maximum value set to 1.0.

650 Fig. 3. Leaf area index (LAI) of the tree species (component LAI) estimated by  
651 combining the leaf-seasonality data (until August 25) with the litter-trap data (after  
652 August 25).

653 Fig. 4. Top graph: Leaf area index (LAI) of the entire canopy and of the dominant,  
654 codominant, and suppressed tree groups, and the understory layer (*Sasa* dwarf  
655 bamboo), estimated by the proposed method. Bottom graph: The corresponding  
656 fractions of total LAI for each group.

657 Fig. 5. Leaf area index (LAI) of the canopy (excluding *Sasa*) estimated by three  
658 methods: the method proposed in this study (which combines litter-trap data with  
659 leaf-seasonality observations), the LAI-2000 canopy analyzer, and the Tracing

660 Radiation and Architecture of Canopies (TRAC) approach. The LAI values for the  
661 LAI-2000 and TRAC approaches were estimated from the observed plant area index  
662 (PAI) under the assumption that the stem area index (SAI) equaled 0.8. The error  
663 bar represents standard error except for TRAC. The error bar of TRAC represents  
664 the range between the minimum and maximum of the LAI values calculated with  
665 the four groups of the parameter setting.

666

667 Fig. 6. Fraction of total LAI accounted for by the major species at the study site  
668 (*Betula*, *B. ermanii* and *B. platyphylla* combined; *Quercus crispula*; *Magnolia*  
669 *obovata*; *Acer rufinerve*; *Tilia japonica*; *Hydrangea paniculata*; and *Viburnum*  
670 *furcatum*) in late summer (August 25) versus the corresponding fraction of total  
671 basal area (Ohtsuka et al., 2005). Error bars represent the standard error.

672

673 Table 1. Sample shoots for the *in-situ* leaf-seasonality observation

674		ID of the	Height of	Leaf	Maximum
675		individual	the shoot	positions	number of leaves

701 Table 2. Leaf mass per unit leaf area (LMA; g m<sup>-2</sup>) of the major tree species

702	Species	Position	Mean	s.d.	Sample size	std. error
703	Dominant group					
704	<i>Betula ermanii</i>	top	92.2	4.3	5 leaves	2.1
705		bottom	62.3	3.6	5 leaves	1.8
706		<b>average</b>	<b>76.3</b>	---	---	<b>2.8</b>
707	<i>Quercus crispula</i>	top	81.9	15.7	13 leaves	4.5
708		bottom	58.8	10.0	8 leaves	3.8
709		<b>average</b>	<b>69.7</b>	---	---	<b>5.9</b>
710	<i>Magnolia obovata</i>	top	91.6	0.1	2 leaves	0.1
711		bottom	44.0	0.2	2 leaves	0.2
712		<b>average</b>	<b>64.9</b>	---	---	<b>0.2</b>
713	<i>Fagus crenata</i>	top	79.9	6.1	5 leaves	1.6
714		bottom	52.0	3.5	2 leaves	4.3
715		<b>average</b>	<b>64.9</b>	---	---	<b>2.6</b>
716	(Mean of averages)		69.0	---	---	<b>5.6</b>
717	Codominant group					
718	<i>Acer distylum</i>	top	44.0	2.3	5 leaves	1.2
719		bottom	24.6	2.3	5 leaves	1.2
720		<b>average</b>	<b>33.4</b>	---	---	<b>1.7</b>
721	<i>Acer rufinerve</i>	top	64.0	6.8	5 leaves	3.4
722		bottom	31.3	2.5	5 leaves	1.3
723		<b>average</b>	<b>45.7</b>	---	---	<b>3.6</b>
724	<i>Acanthopanax</i>	top	42.5	1.3	5 leaves	0.7

725	<i>sciadophylloides</i>	bottom	27.7	0.4	5 leaves	0.2
726		<b>average</b>	<b>34.6</b>	---	---	<b>0.6</b>
727	(Mean of averages)		37.9 <sup>1)</sup>	---	---	<b>6.9</b>
728	(Mean of averages, <i>Acer</i> only)		39.5 <sup>2)</sup>	---	---	<b>9.1</b>
<hr/>						
729	Suppressed group					
730	<i>Hydrangea paniculata</i>	top	39.9	3.8	5 leaves	1.9
731		bottom	25.0	2.0	5 leaves	1.0
732		<b>average</b>	<b>31.9</b>	---	---	<b>2.1</b>
733	<i>Viburnum furcatum</i>	top	43.3	1.9	5 leaves	0.9
734		bottom	43.5	4.3	5 leaves	2.1
735		<b>average</b>	<b>43.4</b>	---	---	<b>2.3</b>
736	(Mean of averages)		37.6 <sup>3)</sup>	---	---	<b>8.5</b>

737 Note:

738 “top” means leaf samples from the highest part of the tree crown; “bottom” means the leaf  
739 samples from the lowest part of the tree crown; “s.d.” means standard deviation; “std. error”  
740 means standard error (standard deviation of the mean). The boldfaced “**average**” values means  
741 the averaged LMA based on equation (8), whereas the “mean of averages” means the  
742 arithmetic mean of the **averaged** LMA.

743 1) This value was used as the surrogate LMA for all other codominant species, including *T.*  
744 *japonica*, *S. alnifolia*, and *K. pictus*.

745 2) This value was used as the surrogate LMA for all other *Acer* species.

746 3) This value was used as the surrogate LMA for all other suppressed species.
