Bulk-edge correspondence in topological pumping

Y. Hatsugai\textsuperscript{1} and T. Fukui\textsuperscript{2}  
\textsuperscript{1}Division of Physics, University of Tsukuba, Tsukuba 305-8571, Japan  
\textsuperscript{2}Department of Physics, Ibaraki University, Mito 310-8512, Japan  
(Dated: July 22, 2016)

The topological pumping proposed in ’80s and recently realized by cold atom experiments\textsuperscript{1,2} is revisited from a view point of the bulk-edge correspondence. For a system with boundaries, a new form of the pumped charge is derived by the Berry connection in the temporal gauge, that corresponds to the shift of the center of mass (CM). Even with boundaries, the pumped charge is carried by the bulk and its quantization is guaranteed by the discontinuities of the CM associated with the edge states. This is a modified Laughlin argument based on the local $U(1)$ invariance although physics behind is quite different.

Many of the theoretical ideas for the topological phases and gauge structures of matter are now directly measured experimentally where quantum coherence and structures are under the ultimate control and one can handle or even synthesize dimensions \textsuperscript{23, 24}. One of the most clear and fundamental examples is a topological pump proposed long time ago \textsuperscript{1}, where the time is used as a synthetic dimension and the topological effects in the QHE in 2D is realized in a simple one dimensional system. Even though the proposal is quite old as the QHE, it took so long time until its experimental realization in cold atoms \textsuperscript{2, 3}, and intense studies have just began. Although the bulk-edge correspondence is fundamental in topological phases, it has never been applied to this topological pump. Here we have first made the role of the edge states clear in the topological pump. In this letter, a new expression of the pumped charge is derived by the Berry connection for the system with boundaries. In the adiabatic limit, the contribution of the the bulk and the edge are clearly separated. The pumped charge is carried by the bulk but its quantization is guaranteed by the locality of the edge states. Local $U(1)$ gauge symmetry as the charge conservation is crucially important but plays a role different from the QHE. Namely, in the QHE, the right- and left-edge states are always paired on the Fermi surface, whereas in the pumping, they can be separately observed at different times. Physically this is a fractionalization of the electron into the massive Dirac fermions carrying half charge quantum.

Let us consider a many body topological pump by the time dependent one dimensional hamiltonian of lattice free fermions of $L_z$ sites

$$H(\theta, t) = \sum_j \left[ -t^\phi_j c_j \right] ,$$

where $t^\phi_j = t \exp[-i\phi j / L_z]$. The twist $\theta$ is introduced to define the current operator as well as the Berry connection for a generic many-body state. The time dependent potential $v_j(t)$ can be any if it is periodic as $v_{j+q}(t) = v_j(t)$ where $q$ is a positive integer. For simplicity, we choose as $v_j(t) = -2t_q \cos(2\pi j / L_z - 2\pi \phi)$, $\phi = p/q$ with mutually prime $p$ and $q$. This is equivalent to the
2D QHE under a periodic potential \([4, 5, 6, 7, 8]\). When mapping back to the QHE in 2D, the time as a synthetic dimension corresponds to the momentum in \(y\) direction \((\frac{2\pi t}{L_x} \to k_y)\). By writing the one particle state as \(|\psi\rangle = \sum_j \psi_j c_j^\dagger |0\rangle\), the wave function \(\psi_j\) satisfies the Harper equation, 
\[-t_y^2 \psi_j - t_x 2 \pi \phi_j \psi_j - (t_y^2) \psi_{j+1} = E_L \psi_j.\]
The time-reversal (TR) is broken by a finite \(\theta\) but is recovered by taking the \(\theta \to 0\) limit after the calculation. The pumping period, \(T\), controls the adiabaticity of the pumping. For simplicity, we take \(T = 2\pi\) and control the adiabaticity by the energy scale of \(t_x\) and \(t_y\).

Two boundary conditions are discussed. One is the open boundary condition with edges, \(\psi_0 = \psi_{L_x} = 0\) and the other is periodic one for the bulk \(b\): \(\psi_{j+L_x} = \psi_j\). The many body eigenstate of the snap shot Hamiltonian \(H(t)\) is given by specifying a set of occupied one particle states \(\{\ell_j\}\) as \(|\alpha\rangle = \prod_j (\sum_{\ell_j} c_j^\dagger |0\rangle\).

Using the current operator 
\[J = \frac{1}{L_x} \frac{e^{-i\theta/L_x}}{\hbar} \sum_j c_j^\dagger c_{j+1} + \text{h.c.} = h^{-1} \partial_\theta H(\theta, t),\]
the measured current at the time \(t\), \(\delta j = \langle G(t) |J| G(t)\rangle - \langle g(t) |J| g(t)\rangle\), is evaluated by the adiabatic approximation \([1]\) assuming a finite energy gap above the snap shot ground state \(|g(t)\rangle\), \(H(\theta, t)|g\rangle = |g\rangle E\). The state \(|G(t)\rangle\) is a true many body state that obeys the time dependent Schrödinger equation, \(i\hbar \partial_\theta |G(t)\rangle = H(\theta, t)|G(t)\rangle\). It reads \(\delta j = -i B\), \(B = \partial_\theta A_\mu - \partial_\theta A_\rho\) where \(B\) is a field strength of the Berry connection \(A_\mu = \langle g|\partial_\mu g|\rangle, \mu = \theta, t\).

Note that \(\langle g(t) |J| g(t)\rangle_{\theta = 0} = 0\) due to the TR invariance. Since the field strength \(B\) is gauge invariant for the gauge transformation \(|g'\rangle = |g\rangle e^{i\chi}\), \(A'_\mu = \langle g'|\partial_\mu g'|\rangle = A_\mu + i\partial_\theta \chi\), let us take a temporal gauge by imposing a gauge condition, \(A_\theta^{(t)} = 0\), which is quite useful for the discussion of the pumping. Then the field strength is given as \(B = -\partial_\theta A^{(t)}\). Now we have a pumped charge between the time period \([t_a, t_b]\) as

\[\Delta Q_{[t_a, t_b]} = \int_{t_a}^{t_b} dt \delta j_x = \int_{t_a}^{t_b} dt \partial_\theta A^{(t)}|_{t_a}^{t_b} = \int_{t_a}^{t_b} dt \partial_\theta A^{(t)} = iA^{(t)}|_{t_a}^{t_b},\]

where the integration over \(t\) has been carried out but it needs a special care, as discussed later. For any (regularly) gauge fixed many body state \(|g\rangle\), the state in the temporal gauge is given by \(|g^{(t)}(\theta, t)\rangle = |g(\theta, t)\rangle e^{i\chi(\theta, t)}\), with the phase factor, \(\chi\), that is path dependent and is explicitly given as \(\chi(\theta, t) = \int_0^t d\tau A_\theta(\theta, \tau) + i \int_0^t d\tau \partial_\theta A_\rho(\theta, 0)\). It surely satisfies the gauge condition, \(A_\theta^{(t)}(\theta, t) = 0\) and one has

\[A^{(t)}(\theta, t) = A_\theta(\theta, t) - \partial_\theta \int_0^t d\tau A_\theta(\theta, \tau) - A_\rho(\theta, 0).\]

This is gauge invariant: it is directly confirmed but is clear in a discretized form \([5, 6]\) as shown in Fig.1. Substituting this into \(\Delta Q\) above, we have a pumped charge in a novel gauge invariant form. The discussion up to this point is general and applicable for both with/without edges.

Now let us consider a system with edges by imposing the open boundary condition. In this case, the twist of the hopping \(e^{-i\theta/L_x}\) is gauged out by the many body gauge transformation

\[U(\theta) = \prod_j e^{-i\theta n_j(j-j_0)/L_x}, j_0 = L_x/2,\]

which operates for the fermion operator as \(U_G U^\dagger = e^{i\theta/L_x} \varepsilon_j\) and we have \(|g(\theta)\rangle = U(\theta)|g_0\rangle\) where \(|g_0\rangle\) is a snap shot ground state of the Hamiltonian \(H(0, t)\). Then noting that \(A_t = \langle g|\partial_\theta g|\rangle = \langle g_0|\partial_\theta g_0|\rangle = \theta\) independent and \(A_\theta = \langle g_0|k^\dagger \partial_\theta U|g_0\rangle\), the Berry connection in the temporal gauge for the system with edges is

\[A^{(t)}_\theta = -i \int_0^t d\tau P(t) - P(0), P(t) = \sum_j x_j \rho_j(t),\]

where \(\rho_j(t) = \langle g_0(t)|n_j|g_0(t)\rangle\), \(x_j = \frac{i\theta_0}{L_x}\) and \(P(t)\) is the CM. Now we have the pumped charge as

\[\Delta Q_{[t_a, t_b]} = P(t_b) - P(t_a).\]

Note that this is only well defined for a system with boundaries. We also stress that the CM derived here is distinct from the Zak phase for infinite systems. We assume \(P(t)\) is a CM measured for the snap shot ground state in contact with a particle reservoir; that is, the system is specified by the chemical potential \(\mu\) and the temperature is sufficiently low. It should be also distinguished from the CM of the time dependent wave function \(\sum_j x_j \langle G(t)|n_j|G(t)\rangle\), which is recently observed in real experiments \([12, 13, 20]\). Even though the fermi energy is in the bulk gap, when the one particle energy of the edge state coincides to the fermi energy, the many body gap of the snap shot Hamiltonian necessarily closes and the edge state becomes suddenly occupied/unoccupied (See Fig.2). This sudden change of the snap shot ground state causes singularities (discontinuities) in \(P\) since the edge state is spatially localized and its contribution to the normalized CM is \(\pm 1/2\) in the limit \(L_x \to \infty\). This is inevitable since topologically non trivial ground state is associated with the edge states passing through the gap. Then labeling the gap closing time’s by \(t_i\)’s \((t_i < t_{i+1}, i = 1, 2,\ldots)\),

![FIG. 1. (a) The Berry connection \(A^{(t)}\) in the temporal gauge and (b) its lattice analogue \([25]\).](image-url)
\(i = 1, 2, \cdots\) and dividing the period into the time intervals without the singularities (patch-working in the time domain), the total pumped charge in a single period \(T\) is given as

\[
\Delta Q^c = \sum_i \int_{t_i}^{t_{i+1}} dt \partial_t P(t) = \sum_i \left[ P(t_{i+1}^-) - P(t_i^+) \right]
\]

\[
= - \sum_i \left[ P(t_i^+) - P(t_i^-) \right] = - \sum_i \Delta P(t_i),
\]

where \(t_i^+ \equiv t_i \pm 0\) and \(\Delta P(t_i) \equiv P(t_i^+) - P(t_i^-)\) is a discontinuity of the CM at \(t_i\). Also we used the periodicity of the CM in the adiabatic limit \(P(t+T) = P(t)\), which follows from the periodicity of the hamiltonian \(H(t+T) = H(t)\). This simple expression can be understood as a bulk-edge correspondence in time domain. We put "e" to mark the expression for the system with edges. Note here that \(P\) is only well defined with edges and can not be defined for a system with periodic boundary condition. Depending on the position of the edge state that cuts the fermi energy and the way it does, this discontinuity is determined as

\[
\Delta P(t_i) = \begin{cases} 
-1/2 & \text{Right : become unoccupied} \\
+1/2 & \text{Left : become unoccupied} \\
-1/2 & \text{Right : become occupied} \\
+1/2 & \text{Left : become occupied},
\end{cases}
\]

where “Right” implies the edge state is localized near the boundary \(j = L_x\) and the “Left” is for the edge states near the boundary \(j \sim 0\).

Since the pair of the discontinuity coincides to the winding of the corresponding edge state energy around the “hole” (that corresponds to the energy gap) on the Riemann surface \(\mathbb{O}\), total discontinuity is given by the winding number \(I_M\) of the edge states

\[
\sum_i \Delta P(t_i) = -I_M, \quad \Delta Q^c = I_M,
\]

where we assume that the fermi energy is in the \(M\)-th energy gap from below. This algebraic definition of the winding number is only possible for the Harper equation, that is, only for special form of the \(v_j(t)\). The relation is generically justified by defining the winding number \(I_M\) as the number of paired edge states with suitable sign depending on the direction of the crossing of the spectral flow with the fermi energy. This is a modified Laughlin argument \(\mathbb{O}\) which is widely used for the topological number of edge states for various topological phases \(\mathbb{O}, 10, 11\). Since the total number of particles is conserved, the gapless times \(t_i\)’s that correspond to the (dis)appearance of the edge state are paired (irrespective to the position). It guarantees the quantization of the total pumped charge \(\Delta Q^c\) as an integer since even number of additions of \(\pm 1/2\) is an integer. It is a consequence of the local \(U(1)\) gauge symmetry as the Laughlin argument, but has sharp contrast to the QHE in which contribution of the edge states to the Hall conductance are always integers in the process of a unit flux penetration, since the right/left edge states are always paired on the Fermi surface. This \(\pm 1/2\) contribution can be understood as a fractionalization of electrons into massive Dirac fermions \(27, 28\).

Also counting the topological number with discontinuities here should be compared with the counting of the singularities of the \(n\)-invariant for the Atiyah-Patodi-Singer index theorem \(29, 30\). Here we have clarified the close inter-relation between the topological nature of the discontinuities and local \(U(1)\) gauge symmetry. This is not just a math but plays a crucial role in the recent experiments \(2, 3\).

As an example, we calculated the CM, \(P(t)\), numerically for \(\phi = 2/7\) and \(L_x = 1750\) and \(L_x = 350\). By the clear finite size effects, the discontinuities deviates from \(\pm 1/2\) but approaches to the quantized values \(\pm 1/2\) by the limit \(L_x \rightarrow \infty\). In this case, we have \(\Delta Q^c = -2\).

FIG. 2. (a) One particle spectrum \(E_{1L}(t)\) and the fermi energy (blue line): \(t_0 = t_9 = 1, \phi = 2/7\) and \(L_x = 1750, 350\). (b) Enlarged spectrum near the fermi energy. (c) The CM, \(\hat{P}(t)\), with edges by numerical calculation. \(\Delta P(t_i) = -0.499503(-0.4954), 0.496542(0.487094), 0.498412(0.494115), 0.497435(0.491002), 0.497435(0.491092), 0.498412(0.494115), 0.496542(0.487094), \) and \(-0.499503(-0.4954)\) for \(i = 1, \cdots, 8\). \(\sum_i \Delta P(t_i) = 1.98577(1.9538)\).
Note that although the total pumped charge is governed by the discontinuity $\sum \Delta P(t_i)$ due to the edge states, pumped charge is not carried by singularities caused by the edge states. The charge is still carried by the bulk as we explain below. This is the bulk-edge correspondence in the topological pumping. As one can see in Fig.[2] the charge is pumped in the intervals between the singularities (red lines), which is the bulk contribution. Even though the system has boundaries, the effects of the edges are negligible for the bulk state since the one particle state of the bulk is extended and the amplitude near the boundaries is vanishing in the limit $L_x \to \infty$.

Although the CM is ill-defined for bulk (both for a periodic/infinite system), the pumped charge is well-defined as discussed by Thouless[1]. As for an infinite system, the one particle state is given by the Bloch state $\psi_j(x)$, and the corresponding CM is given by $A^{(t)}_b = \langle 0 | \partial_\tau \hat{A}_\theta(x) | 0 \rangle$. The fermi energy is in the $M$-th gap, one has

$$A^{(t)}_b = \langle 0 | \partial_\tau \hat{A}_\theta(x) | 0 \rangle = \int_0^\infty \frac{dk_x}{2\pi} \hat{a}^{(t)}_{k_x},$$

and

$$a^{(t)}_{k_x} = \text{Tr}_M A^{(t)}_{k_x},$$

where the limit $L_x \to \infty$ is taken and additional gauge condition $\hat{a}^{(t)}_{k_x} = \text{Tr}_M u^\dagger \partial_{k_x} u = 0$ is imposed. Also we put “b” to specify that it is purely from bulk. Using the gauge invariant form of the temporal gauge,

$$a^{(t)}_{k_x}(k_x,t) = a_{k_x}(k_x,t) - \partial_{k_x} \int_0^t \partial_\tau a_{k_x}(k_x,\tau) - a_{k_x}(k_x,0),$$

the time derivative of $A^{(t)}_b$ is written by the field strength of the Bloch state, $b = \partial_{k_x} a_{k_x} - \partial_t a_{k_x} = -\partial_t a^{(t)}_{k_x}$. Now the bulk contribution of the pumped charge between the time period $[t_a,t_b]$ is written as [1]

$$\Delta Q^b_{[t_a,t_b]} = i \int_{t_a}^{t_b} dt \partial_\tau A^{(t)}_b = \frac{1}{2\pi i} \sum_{j=1}^M \int_{t_a}^{t_b} \sum_{k_x} \Delta^{k_x} ds \partial_{k_x} b(k_x,t).$$

It implies that $i\partial_\tau A^{(t)}_b$ is an effective CM of the bulk, even though the CM itself is not well defined.

To demonstrate the contribution of the pumping with edges is from the bulk, let us define a pumped charge between the time period $[t_a,t_b]$ by compensating (skipping) the singularities from the edges as

$$\Delta Q^e_{[t_a,t_b]} = P(t_b) - P(t_a) - \int_{t_a}^{t_b} d\tau \sum_i \Delta P(t_i) \delta(\tau - t_i).$$

This is a bulk contribution to the CM for the system with edges. According to the consideration here, we expect this bulk contribution $\Delta Q^e_{[t_a,t_b]}$ asymptotically approaches to $\Delta Q^b_{[t_a,t_b]}$ in the large system. We have numerically evaluated them for $\phi = 2/7$ and shown in Fig[3]. They show clear coincidence within numerical errors, indicating the relation between the bulk and the edges.

![FIG. 3. Pumped charge between the time interval [0, t]. The red line is by the bulk (Bloch states) $\Delta Q^b_{[0,t]}$. The shifted pumped charge $\Delta Q^e_{[0,t]}$'s are shown for $L_x = 140$ (blue) and $L_x = 1750$ (black) lines. The parameters are the same as Fig[2].](image)

The pumped charge by bulk in a cycle is given by the Chern number $C_M$ of the Berry connection $a_u$ as $\Delta Q^b = \Delta Q^b_{[0,T]} = C_M$. Now we have established the physical bulk-edge correspondence in the topological pumping as

$$\Delta Q^e = \Delta Q^b$$

that gives the relation between the two topological invariants as was also shown in the QHE as

$$I_M = C_M.$$
adiabatic but the edge states is well described by the sudden approximation. It causes excitation across the gap, which eventually results in accumulation/depletion of the surface charges after one cycle. These two conditions, as the bulk is adiabatic and the edge is sudden, are conflicting requirements, if one requires both limits rigorously. Then in the experiment, it may not be easy to observe exact quantization of the pumped charge, especially for cases with high Chern numbers. We have also confirmed consistency of the argument by a direct numerical integration of the Liouville–von Neumann equation for the density matrix.

We thank stimulating discussions on the topological pump with Y. Takahashi, S. Nakajima and M. Lohse. The work is supported in part by KAKENHI from JSPS (Nos.26247064, 25400388,16K13845).
