18

19 **Abstract**

20 Essential parameters for the applications of ^{36}Cl as a tracer in groundwater studies include
21 the initial $^{36}\text{Cl}/\text{Cl}$ ratio, at the time of recharge, and/or the natural background deposition flux of
22 ^{36}Cl in the recharge area. To facilitate the hydrological use of ^{36}Cl in central Japan, this study
23 aims to obtain a precise estimate of the long-term average local ^{36}Cl flux and to characterize its
24 seasonal variability. ^{36}Cl in precipitation was continuously monitored in Tsukuba, central Japan

1 over a period of >5 years. The ^{36}Cl flux showed a clear seasonal variation with an annual peak
2 during the spring, which is attributed to the seasonal variability of tropopause height. The
3 long-term average ^{36}Cl flux ($32 \pm 2 \text{ atoms m}^{-2} \text{ s}^{-1}$), estimated from the measured data, is
4 consistent with the prediction from the ^{36}Cl latitudinal fallout model scaled using the global
5 mean production rate of $20 \text{ atoms m}^{-2} \text{ s}^{-1}$. The initial $^{36}\text{Cl}/\text{Cl}$ ratio was estimated to be $(41 \pm 6) \times$
6 10^{-15} , which is similar to that of pre-bomb groundwater in the Tsukuba Upland. An observation
7 period covering an 11-year solar cycle would yield more accurate estimates of the values, given
8 the increased ^{36}Cl flux during the solar minimum.

9

10 Keywords: ^{36}Cl , flux, precipitation, accelerator mass spectrometry

11

12 1. Introduction

13 The long-lived radionuclide ^{36}Cl , with a half-life of 301,000 years, has been successfully
14 used as an environmental tracer in groundwater studies (e.g., Phillips and Castro, 2003). The
15 widespread use of ^{36}Cl in such studies is largely attributed to the advent of accelerator mass
16 spectrometry (AMS) in the late 1970s (Elmore et al., 1979). Because of the extremely low
17 abundance of ^{36}Cl in the environment (typically $10^{-12}\text{--}10^{-15}$), AMS is practically the only
18 technique capable of detecting and quantifying natural levels.

19 Hydrological investigations using ^{36}Cl have been thoroughly reviewed in previous studies
20 (Bentley et al., 1986a; Fabryka-Martin et al., 1987; Fontes, 1989; Fontes and Andrews, 1994;
21 Phillips, 2000). Owing to the long half-life of ^{36}Cl , its most common application is the dating of
22 very old groundwaters in large-scale aquifers such as the Great Artesian Basin of Australia
23 (Bentley et al., 1986b; Torgersen et al., 1991; Love et al., 2000), the Milk River aquifer in
24 Alberta, Canada (Phillips et al., 1986; Nolte et al., 1990, 1991), and the Aquia aquifer in

1 Maryland, USA (Purdy et al., 1987, 1996). The ^{36}Cl bomb pulse, which originates from nuclear
2 tests in the 1950s, has also been used to trace young groundwater (Cook and Robinson, 2002;
3 Tosaki et al., 2011b). Essential parameters for both of these applications include the initial
4 $^{36}\text{Cl}/\text{Cl}$ ratio, at the time of recharge, and/or the natural background deposition flux of ^{36}Cl in the
5 recharge area.

6 Atmospheric ^{36}Cl is predominantly produced in the stratosphere (~54%–90%; Hugge et al.,
7 1996; Masarik and Beer, 1999) by cosmic-ray-induced spallation of ^{40}Ar at a global mean rate
8 of approximately 20 atoms $\text{m}^{-2} \text{s}^{-1}$ (Hugge et al., 1996; Masarik and Beer, 1999, 2009). The
9 aerosol-bound ^{36}Cl and gaseous H^{36}Cl in the stratosphere are transported out of the stratosphere
10 and across the tropopause within ~2 years (Synal et al., 1990). They are removed quickly from
11 the troposphere by wet or dry deposition, while mixing with stable chlorine in the atmosphere.
12 The mean residence time of ^{36}Cl in the troposphere is expected to be on the order of weeks,
13 according to estimates of atmospheric aerosol residence times (Turekian et al., 1977; Bleichrodt,
14 1978; Raisbeck et al., 1981).

15 Atmospheric chlorine is mainly of oceanic origin, and as a result decreases exponentially
16 with increasing distance from the coast (Eriksson, 1960). Consequently, the $^{36}\text{Cl}/\text{Cl}$ ratios in
17 precipitation and infiltrating water are controlled mainly by the latitudinal pattern of
18 atmospheric ^{36}Cl deposition (Lal and Peters, 1967; Bentley et al., 1986a) and the delivery of
19 marine-derived Cl. As an example, the distribution of $^{36}\text{Cl}/\text{Cl}$ ratios over the continental United
20 States has been estimated by Bentley et al. (1986a), who found low values in coastal areas and
21 higher values in the interior. This distribution pattern has been confirmed by measured $^{36}\text{Cl}/\text{Cl}$
22 values for pre-bomb groundwaters (Davis et al., 2003; Moysey et al., 2003). Once the initial
23 $^{36}\text{Cl}/\text{Cl}$ value is known, the ^{36}Cl flux can be reasonably estimated by using a mass balance
24 equation for ^{36}Cl and Cl at the ground surface (Andrews et al., 1994).

1 The spatial distribution of ^{36}Cl in precipitation during the spring of 2007 was investigated on
2 a continental scale in Europe (Johnston and McDermott, 2008), yielding a distribution of the
3 $^{36}\text{Cl}/\text{Cl}$ ratio similar to that in the United States (Moysey et al., 2003). Thus, the most direct
4 approach in obtaining the initial value and/or the background flux is to monitor ^{36}Cl in
5 precipitation (for several years to obtain reasonable estimates) (Davis et al., 1998). However,
6 only a few studies have continuously measured ^{36}Cl deposition fluxes for 1–2 years, at a time
7 resolution finer than monthly (Hainsworth et al., 1994; Knies et al., 1994; Santos et al., 2004).
8 These earlier studies revealed a seasonal trend in the ^{36}Cl flux, with a peak in spring due to air
9 exchange between the stratosphere and the troposphere. A longer observation period would
10 allow seasonal changes to be distinguished from short-term fluctuations.

11 For evaluating ^{36}Cl flux, chlorine recycling as CH_3Cl is another issue that should be
12 mentioned. Ice core data from Greenland (Synal et al., 1990) showed that the bomb-derived
13 enhanced ^{36}Cl flux returned to pre-bomb level in around 1985. In a global-scale study (Scheffel
14 et al., 1999; Blinov et al., 2000), however, measured ^{36}Cl flux around the early 1990s was still
15 up to one order of magnitude higher than model prediction (Lal and Peters, 1967). They
16 attributed it to storage of chlorine (including bomb-produced ^{36}Cl) in the biosphere and its
17 subsequent release in the form of CH_3Cl into the troposphere. Later in Europe in 2007, Johnston
18 and McDermott (2008) concluded that ^{36}Cl flux has returned to pre-bomb value.

19 This study aims to obtain a precise estimate of the long-term average local ^{36}Cl flux and to
20 characterize its seasonal variability. The results will facilitate the use of ^{36}Cl in hydrological
21 applications in central Japan. In addition, we investigate the possible influence of chlorine
22 recycling as CH_3Cl , which may limit the use of ^{36}Cl as a young groundwater tracer. Our study,
23 which covers a period of >5 years, highlights a characteristic seasonal variation in local ^{36}Cl
24 flux, and constrains estimates of the annual average ^{36}Cl flux and the initial $^{36}\text{Cl}/\text{Cl}$ value.

1

2 **2. Materials and methods**

3 *2.1. Sample collection*

4 Monthly bulk precipitation samples were collected over a period of >5 years (from April
5 2004 to December 2009) on the roof of the Physical Sciences Building, University of Tsukuba
6 (36°06'N, 140°06'E), located on the Tsukuba Upland in central Japan (Fig. 1). The climate of
7 the area is humid temperate, with an annual precipitation of 1246 ± 178 mm and an annual mean
8 temperature of $13.4 \pm 0.6^\circ\text{C}$ (average values for 1951–2000; meteorological data at the
9 Aerological Observatory in Tsukuba, which is located 6 km southeast of the sampling site). The
10 precipitation collector consists of a polyethylene (PE) funnel (diameter of 15 or 21 cm), a
11 high-density polyethylene (HDPE) bottle (3 or 5 L), a specially designed piece of glassware
12 with a ping-pong ball inside (to prevent evaporative loss of the sample; e.g., Shimada et al.,
13 1994; Yabusaki et al., 2006), and silicon plugs used to make connections. Two collectors were
14 usually set up to ensure sufficient monthly precipitation sample volumes for the measurement of
15 ^{36}Cl , even in cases where the monthly precipitation amount was significantly smaller than
16 normal.

17 *2.2. Analytical methods*

18 After collection, the sample volumes were measured and aliquots were extracted for the
19 analysis of major dissolved ions. In cases where the sample volume of one bottle was not
20 sufficient for the analysis of ^{36}Cl , two bottles of the sample were combined before the volume
21 measurement. The samples for dissolved ion analysis were passed through 0.20 μm membrane
22 filters (25HP020AN, Advantec, Tokyo, Japan). For the samples collected between April and
23 November 2004, Cl^- concentrations were measured by ion chromatography (QIC Analyzer,
24 Dionex, Sunnyvale, CA, USA) at the Watershed Environment Laboratory, Graduate School of

1 Life and Environmental Sciences, University of Tsukuba. The remaining samples (collected
2 between December 2004 and December 2009) were analyzed for the concentrations of Na^+ ,
3 Mg^{2+} , Ca^{2+} , and Cl^- by ion chromatography (Ion Analyzer IA-100, Dkk-Toa, Tokyo, Japan) at
4 the Tandem Accelerator Complex, Research Facility Center for Science and Technology,
5 University of Tsukuba.

6 Prior to ^{36}Cl analysis, samples were first filtered through glass microfiber filters (GF/B,
7 Whatman, Maidstone, UK) and then through 0.45 μm membrane filters (JHWP04700, Millipore,
8 Billerica, MA, USA). An ion exchange system was developed to concentrate sample chloride.
9 The system includes a solution-sending pump (Masterflex L/S variable speed modular drive, No.
10 7553-80, Cole-Parmer, Vernon Hills, IL, USA) with four pump heads and four anion exchange
11 columns. Each pump head uses Tygon tubing (inner diameter, 3.1 mm) to transport the sample
12 into a column. Two systems enabled simultaneous processing of eight samples.

13 Approximately 20 mL (wet volume) of AG 4-X4 anion exchange resin in the free-base form
14 (100–200 mesh; Bio-Rad Laboratories, Hercules, CA, USA) was loaded into 60 mL Bond Elute
15 columns (Varian, Palo Alto, CA, USA). The resin was cleaned on-column using 4 M HNO_3 . The
16 resin was then rinsed with Milli-Q ultrapure water (resistivity > 18 $\text{M}\Omega\cdot\text{cm}$; Millipore), before
17 being conditioned with 0.5 M NH_4OH and 2 M NH_4OH . The resin was then rinsed again with
18 ultrapure water. After loading the sample on the column, the Cl was eluted using 3 M HNO_3 .

19 The samples were then processed using the method described by Tosaki et al. (2011a). All
20 samples were analyzed for $^{36}\text{Cl}/\text{Cl}$ (atomic ratio of ^{36}Cl to stable Cl) using the AMS system
21 installed at the Tandem Accelerator Complex, University of Tsukuba (Sasa et al., 2010), along
22 with diluted NIST ^{36}Cl standards ($^{36}\text{Cl}/\text{Cl} = 1.60 \times 10^{-12}$; Sharma et al., 1990). The overall
23 precision of the system was better than 2% and the measurement background level was $\sim 1 \times$
24 10^{-15} (Sasa et al., 2010). The calculated $^{36}\text{Cl}/\text{Cl}$ ratio of the sample includes the statistical error

1 derived from the uncertainties (1σ) associated with the measurement of the sample, the standard,
2 and the blank.

3

4 **3. Results and discussion**

5 Table 1 gives the chemical composition and ^{36}Cl data of monthly precipitation samples
6 collected over the entire sampling period from 2004 to 2009. The sample for December 2005 is
7 omitted from Table 1 because of the extremely small amount of precipitation during this month
8 (1.0 mm; meteorological data at the Aerological Observatory). From the measured data, the ^{36}Cl
9 deposition fluxes were calculated according to the following equation:

10

11
$$F = \frac{C \times V}{A \times D \times 24 \times 60 \times 60} \quad (1)$$

12

13 where F is the ^{36}Cl deposition flux (atoms $\text{m}^{-2} \text{s}^{-1}$), C is the ^{36}Cl concentration (atoms L^{-1}), V is
14 the collected volume of precipitation (L), A is the cross-sectional area of the top of the funnel
15 (m^2), and D is the length of the sampling period (days). The Cl fluxes were similarly calculated
16 from the Cl^- concentrations using Eq. 1.

17 To ensure sampling efficiency, the collected amount of monthly precipitation was compared
18 with the observed meteorological data from the Aerological Observatory (Fig. 2). A portion of
19 the sample with the greatest monthly precipitation (October 2004) was lost because of overflow
20 from the collector during a typhoon event. For the August 2007 sample, the precipitation
21 amount calculated from the collected volume (60.5 mm) was much greater than the observed
22 meteorological data value (21.0 mm). These two values differ because of the spatial
23 heterogeneity of precipitation; the observed data at ~ 1 km northwest of the study site was also
24 higher than the observed meteorological data value (44.0 mm) from the Terrestrial Environment

1 Research Center (TERC), University of Tsukuba. The majority of the samples plot close to the
2 line of agreement (Fig. 2), suggesting that the sampling efficiency was ~100%. Small sample
3 losses from the collectors due to evaporation would not influence the ^{36}Cl and Cl fluxes because
4 these fluxes are calculated from the collected precipitation volume.

5 The source of Cl^- in precipitation was evaluated by plotting the concentrations of elements
6 predominately of seawater origin (Na^+ and Mg^{2+}) against Cl^- concentrations (Fig. 3). Figure 3a
7 shows an overall enrichment in Mg^{2+} relative to seawater, which may be attributed to Mg^{2+}
8 contributions from wind-blown soil particles. This interpretation is supported by the $\text{Ca}^{2+}/\text{Cl}^-$
9 ratios, which are much higher than those of seawater (calculated from Table 1). The contribution
10 of soil particles seems to be less dominant in high-precipitation months (Fig. 3; see the next
11 paragraph for P/P_{avg}), probably because higher rainfall leads to less incorporation of dust. In
12 contrast, the Na^+/Cl^- ratios of the precipitation are similar to that of seawater (Fig. 3b), which
13 suggests that the vast majority of the Cl in the precipitation originates from seawater (sea spray).
14 The $^{36}\text{Cl}/\text{Cl}$ ratio of seawater is close to the detection limit of AMS, 1×10^{-15} (Argento et al.,
15 2010); consequently, the ^{36}Cl contained in the precipitation samples should reflect production in
16 the atmosphere.

17 Figure 4 shows $^{36}\text{Cl}/\text{Cl}$ ratios in monthly precipitation samples plotted against $1/\text{Cl}^-$. The
18 presence of a positive correlation confirms that $^{36}\text{Cl}/\text{Cl}$ ratios in precipitation are determined
19 primarily by the amount of stable Cl deposition. To examine the effect of varying precipitation
20 amounts (Fig. 4), the data were divided into two groups based on P/P_{avg} , the deviation of the
21 monthly precipitation amount (P) from the average observed monthly precipitation value (P_{avg})
22 at the nearest weather station (i.e., the Aerological Observatory). The data were divided at P/P_{avg}
23 = 1.5, which corresponds to a 50% increase of monthly precipitation. The samples with $P >$
24 $1.5P_{\text{avg}}$ plot below the trend formed by the samples with $P < 1.5P_{\text{avg}}$, which suggests a

1 precipitation dilution effect on Cl^- concentration (Fig. 4).

2 To exemplify the temporal variability of ^{36}Cl and Cl in precipitation, the measured data and
3 calculated flux values for the entire sampling period are presented in Fig. 5. The $^{36}\text{Cl}/\text{Cl}$ ratio
4 exhibits an annual peak, which occurs around June (Fig. 5d). On the other hand, the ^{36}Cl flux
5 exhibits a peak in April–May (Fig. 5f). This difference is attributed to the significant decrease of
6 Cl flux in June (Fig. 5c), which leads to an increase in the $^{36}\text{Cl}/\text{Cl}$ ratio. The most probable
7 cause of this phenomenon is the washout effect by the persistent rain during the East Asian rainy
8 season, which generally occurs from June to mid-July in central Japan. The Cl and ^{36}Cl
9 concentrations were not characterized by obvious seasonal trends (Fig. 5b and e, respectively)
10 because the precipitation dilution effect (discussed above) directly affects both concentrations
11 (Fig. 4).

12 Similar spring maxima in the ^{36}Cl flux have been observed at other locations (Hainsworth et
13 al., 1994; Knies et al., 1994) and for other cosmogenic radionuclides; e.g., ^7Be (e.g., Viezee and
14 Singh, 1980) and ^{10}Be (e.g., Raisbeck et al., 1979). As discussed in these previous studies, the
15 seasonal pattern is attributed to annual variation in the tropopause height (Staley, 1962). Since
16 the tropopause begins to rise rapidly in April or May at mid-latitudes (especially at 30–40°N),
17 stratospheric air masses, rich in ^{36}Cl , are transported into the troposphere and washed out of the
18 atmosphere after approximately 1 week. Figure 6 shows the average monthly values (calculated
19 from the measured data) and corroborates the existence of seasonal trends as described above.
20 Observed increases in the ^{36}Cl flux, other than those that occur in the spring (e.g., October 2004,
21 August 2005, and August 2008; Fig. 5f), are attributed to precipitation amounts (Fig. 5a). This
22 interpretation is supported by the empirical dependence of atmospheric fallout of cosmogenic
23 nuclides on precipitation amount (Knies et al., 1994; Phillips, 2000). However, the correlation
24 between precipitation amount and ^{36}Cl flux is weak, as it is masked by seasonal variation.

1 The seasonal variation is likely to cause a pronounced $^{36}\text{Cl}/\text{Cl}$ peak signal in groundwater
2 recharge between May and June, suggesting that several years would be required to constrain
3 the local initial $^{36}\text{Cl}/\text{Cl}$ value and the annual average ^{36}Cl flux. The measured monthly ^{36}Cl
4 fluxes were averaged for each year to obtain a precise estimate of annual average ^{36}Cl flux
5 (Table 2). The flux values were relatively stable between 2004 and 2007, while they increased
6 for 2008 and 2009 (Fig. 7). This increase may be related to variation in solar activity, as
7 observed for ^7Be (Cannizzaro et al., 2004; Kulan et al., 2006). The smallest annual sunspot
8 numbers were observed for 2008 and 2009 (Fig. 7), which leads to an increase in the production
9 of nuclides due to increased galactic cosmic ray fluxes, while ^{36}Cl production by solar proton is
10 negligible (Hugge et al., 1996). As this period may be regarded as an extreme event, the mean
11 value for 2004–2007 (32 ± 2 atoms $\text{m}^{-2} \text{s}^{-1}$) is expected to be closer to the long-term average
12 flux. This value is in good agreement with the latitudinal dependence of ^{36}Cl fallout (Lal and
13 Peters, 1967), after normalization to the global mean production rate of 20 atoms $\text{m}^{-2} \text{s}^{-1}$ (cf.
14 Hugge et al., 1996; Masarik and Beer, 1999, 2009). Therefore, we conclude that chlorine
15 recycling via CH_3Cl is not evident at present in central Japan.

16 Finally, the annual $^{36}\text{Cl}/\text{Cl}$ values were averaged for 2004–2007 to obtain an estimate of the
17 initial $^{36}\text{Cl}/\text{Cl}$ value, $(41 \pm 6) \times 10^{-15}$. This value is comparable to that of pre-bomb groundwater
18 sampled from an observation well on the premises of the Geological Survey of Japan (sampling
19 depth ~ 50 m) at the Tsukuba Upland, $(31 \pm 3) \times 10^{-15}$. However, Table 2 shows that an even
20 longer period, covering an 11-year solar cycle, is required to obtain a well-constrained initial
21 value. For further consideration of the relationship between the ^{36}Cl flux and solar activity,
22 continuous precipitation sampling is ongoing by the authors.

23

24 **4. Conclusions**

1 The ^{36}Cl deposition flux in central Japan was continuously observed for >5 years. The
2 chlorine in the precipitation was identified as originating from sea spray, indicating that ^{36}Cl
3 produced in the atmosphere dominates in the precipitation in the study area. The ^{36}Cl flux
4 showed a clear seasonal variation with an annual peak during the spring, which is attributed to
5 the seasonal variability of tropopause height. The long-term average ^{36}Cl flux estimated from
6 the measured data is consistent with the prediction from the ^{36}Cl latitudinal fallout model scaled
7 using the global mean production rate of 20 atoms $\text{m}^{-2} \text{ s}^{-1}$. The initial $^{36}\text{Cl}/\text{Cl}$ ratio was
8 estimated to be $(41 \pm 6) \times 10^{-15}$, which is similar to that of pre-bomb groundwater in the
9 Tsukuba Upland. The increase in the ^{36}Cl flux between 2008 and 2009 may have resulted from
10 decreased solar activity during that time. We will further investigate this relationship by
11 continuing the precipitation monitoring for several more years.

12

13 **Acknowledgements**

14 We are grateful to Dr. Kunihiko Nishiizumi for his advice on sample preparation using ion
15 exchange chromatography. Dr. Riki Seki is gratefully acknowledged for her support in the
16 development of the ion exchange system. Ms. Satomi Abe is acknowledged for her help with the
17 preparation of precipitation samples for AMS. The precipitation collector used in this study was
18 designed based on advice from Dr. Shiho Yabusaki. We thank all the members of the AMS
19 Group at the University of Tsukuba for their assistance with the ^{36}Cl measurements. We also
20 thank all the staff at the Tandem Accelerator Complex (University of Tsukuba) for their support
21 during accelerator operation. This research was supported in part by a research grant held by
22 K.S. from the Japan Science and Technology Agency (JST), Grants-in-Aid for Scientific
23 Research (B) (Nos. 21310004, 19300304, and 18360043) from the Japan Society for the
24 Promotion of Science (JSPS), and a research grant (No. 22343) from the Kurita Water and

1 Environment Foundation (KWEF), Japan.

6 Fig. 2. Comparison between the measured precipitation amount and meteorological data.
7

1
2
3 Fig. 3. (a) Na^+ concentrations and (b) Mg^{2+} concentrations plotted against Cl^- concentrations in
4 precipitation. P/P_{avg} denotes the deviation of the monthly precipitation amount (P) from the
5 average observed monthly precipitation value (P_{avg}) at the nearest weather station (see the text
6 for details).
7

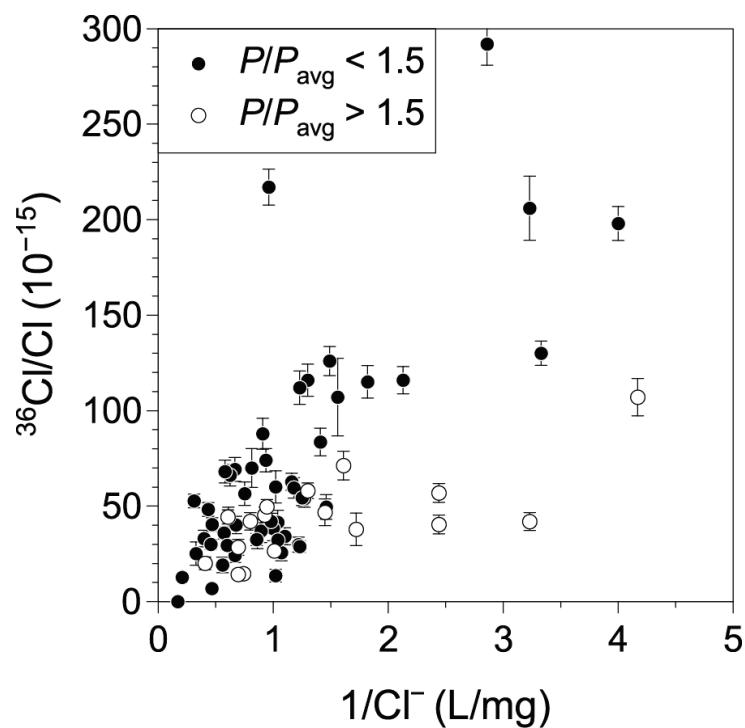

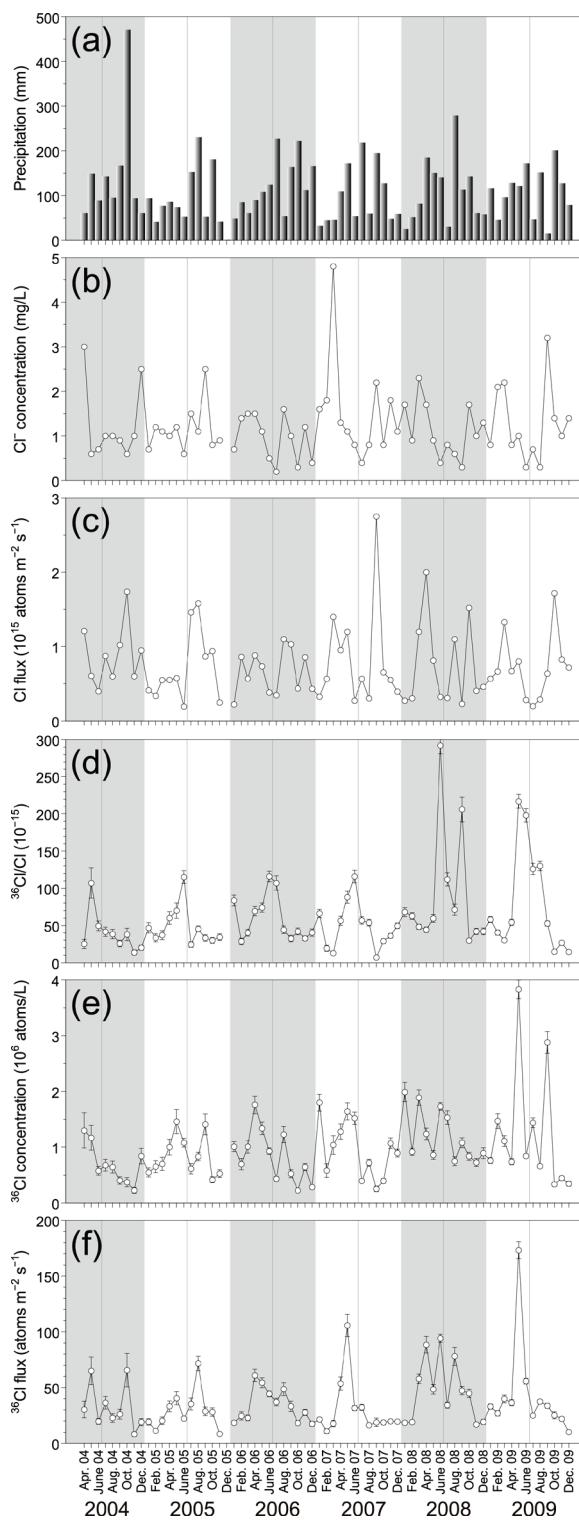

Fig. 4. $^{36}\text{Cl}/\text{Cl}$ ratios in precipitation plotted against the reciprocal of Cl^- concentrations ($1/\text{Cl}^-$).

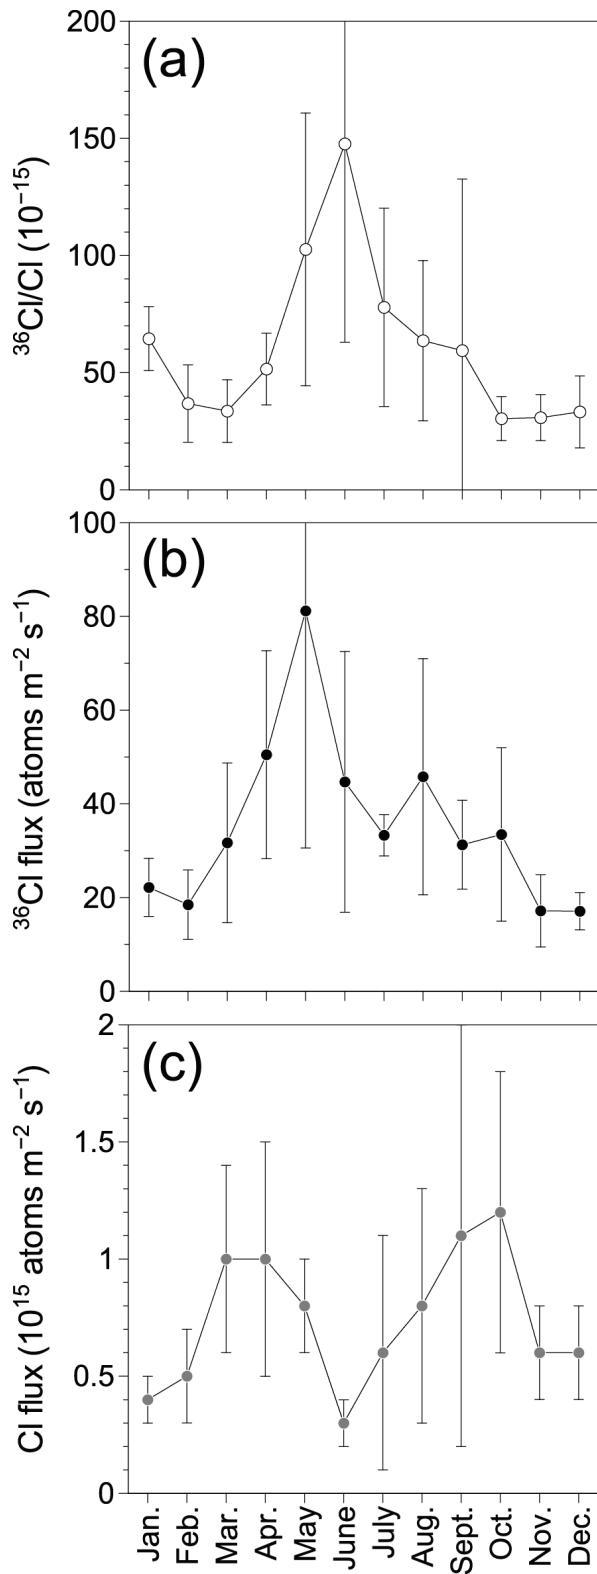

P/P_{avg} denotes the deviation of the monthly precipitation amount (P) from the average observed monthly precipitation value (P_{avg}) at the nearest weather station. The error bars represent the errors involved in measuring ^{36}Cl by accelerator mass spectrometry (see the text for details).

1

2 Fig. 5. Temporal variations in (a) precipitation amount, (b) Cl^- concentration, (c) Cl flux, (d)
 3 $^{36}\text{Cl}/\text{Cl}$ ratio, (e) ^{36}Cl concentration, and (f) ^{36}Cl flux. Shading and vertical lines were added to
 4 visually separate each observation year.

5

1

2 Fig. 6. Seasonal variations in (a) $^{36}\text{Cl}/\text{Cl}$ ratio, (b) ^{36}Cl flux, and (c) Cl flux. The error bars
 3 indicate the standard deviation of 5 or 6 values for each month.

4

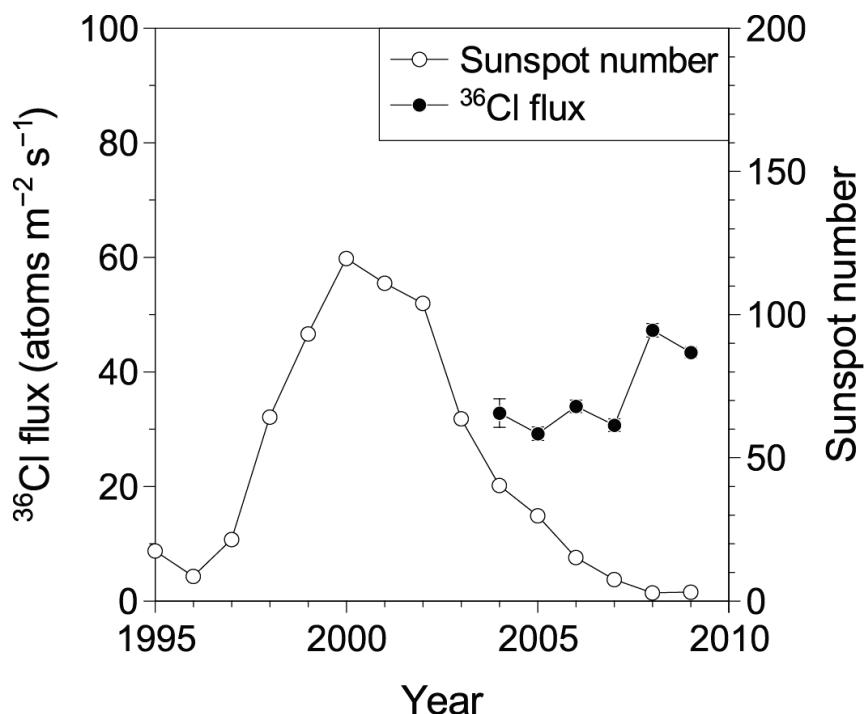

Fig. 7. Comparison between the annual average ^{36}Cl flux and the sunspot number (data from the Solar Influences Data Analysis Center, Belgium).

1 Table 1. Chemical composition and ^{36}Cl data for monthly precipitation samples at Tsukuba.

Month	Precipitation (mm)	Na^+ (mg L^{-1})	Mg^{2+} (mg L^{-1})	Ca^{2+} (mg L^{-1})	Cl^- (mg L^{-1})	Cl flux (10^{15} atoms $\text{m}^{-2} \text{s}^{-1}$)	$^{36}\text{Cl}/\text{Cl}$ ratio (10^{-15})	^{36}Cl concentration (10^6 atoms L^{-1})	^{36}Cl flux (atoms $\text{m}^{-2} \text{s}^{-1}$)

1 Table 2. Annual average ^{36}Cl flux, Cl flux, and $^{36}\text{Cl}/\text{Cl}$ ratio.

Year	^{36}Cl flux (atoms $\text{m}^{-2} \text{s}^{-1}$)	Cl flux (10^{15} atoms $\text{m}^{-2} \text{s}^{-1}$)	$^{36}\text{Cl}/\text{Cl}$ (10^{-15})
2004 ^a	33 ± 3	0.89	37 ± 3
2005 ^b	29 ± 1	0.71	41 ± 2
2006	34 ± 1	0.65	52 ± 2
2007	31 ± 1	0.83	37 ± 1
2008	47 ± 1	0.75	63 ± 2
2009	43 ± 1	0.73	60 ± 1
Average for 2004–2007	32 ± 2	0.77 ± 0.11	41 ± 6
Average for 2004–2009	36 ± 7	0.76 ± 0.09	48 ± 11

^aAverage for April–December 2004.

^bAverage for January–November 2005.

The error on the average values is reported as the standard deviation of the annual values.
