(Received 1 May 2006; published 23 May 2006)

The electronic structure as well as the photoinduced effect were investigated in an antiferromagnetic LaMnO$_3$ film. We found characteristic spin-dependent absorption bands at $\approx 1.6$ eV and $\approx 3$ eV, and ascribed them to the $d$-$d$ transitions into the adjacent Mn$^{3+}$ sites with the parallel and antiparallel spins, respectively. We further observed that the photoexcitation of the down-spin $d$ electrons significantly influences these $d$-$d$ bands, and ascribed the behavior to the photoinduced disorder of the Mn$^{3+}$ spins.

DOI: 10.1103/PhysRevB.73.180403

The photoinduced effects on the strongly correlated electron system is one of the hottest topics in solid state physics both from the fundamental and technical points of view. Especially in the perovskite-type doped manganites, the strong coupling between the spin, charge and orbital degree of freedoms causes a variety of magnetic/electronic phases. Reflecting the strong coupling, the photoexcitation of the $d$ electrons significantly influences the other degrees of freedoms. For example, Ogasawara et al. reported a photoinduced melting of the charge/orbital ordering in La$_{1/2}$Sr$_{1/2}$MnO$_3$ (Ref. 1) and Nd$_{1/2}$Ca$_{1/2}$MnO$_3$ (Ref. 2). On the other hand, Matsuda et al. found a photoinduced disorder of the $t_{2g}$ spins in ferromagnetic (Nd,Sm)$_{0.6}$Sr$_{0.4}$MnO$_3$. They ascribed the photoinduced effect to the strong on-site Hund’s-rule coupling between the local $t_{2g}$ spins and the photoexcited down-spin $e_g$ electrons. Here, we have investigated the photoinduced effect of an antiferromagnetic LaMnO$_3$ with a layered-type spin structure.

The nondoped LaMnO$_3$ is known to show the $d_{3z^2-r^2}$/$d_{3z^2}$ orbital ordering below $T_{CO}(\approx 780$ K), accompanying the cooperative Jahn-Teller distortion of the MnO$_6$ octahedron. This orbital alternation mediates the ferromagnetic exchange coupling within the $ab$ plane, and causes the layer-type spin structure below $T_N(\approx 140$ K). The hole-doping process in LaMnO$_3$ induces the ferromagnetism, which is mediated by strong on-site exchange coupling $J_H$ between the local $t_{2g}$ spins and itinerant $e_g$ carriers (double-exchange interaction). This strong coupling $a priori$ splits the $e_g$ band into the parallel spin state and the antiparallel spin state. Actually, Moritomo et al. have observed the spin-dependent absorption band at $J_H(\approx 3$ eV) in several ferromagnetic manganite films, and ascribed the band to the $d$-$d$ transition between the exchange-split bands ($J$-gap transition). The corresponding absorption band is also expected in the insulating LaMnO$_3$. The interpretation of the electronic structure of LaMnO$_3$, however, is still controversial, even though there exists a long list of experimental and theoretical investigations. Quijada et al. investigated the optical conductivity spectrum of crystalline LaMnO$_3$ against temperature, and found a characteristic transfer of the spectral weight from the ultraviolet region ($\approx 3$ eV) to the visible region ($\approx 2$ eV). They ascribed the former (latter) absorption to the $d$-$d$ transition into the Mn$^{3+}$ site with the parallel (antiparallel) spin. Contrary to this argument, Tobe et al. reported that the anisotropic optical conductivity spectrum of LaMnO$_3$ crystal shows negligible change at $T_N$. Recently, Kovaleva et al. reported spin-dependent transition at $\approx 2$ eV in untwinned LaMnO$_3$ crystal, and Kim et al. reported distinct suppression of the absorption band at $\approx 2$ eV around $T_N$ in the epitaxial LaMnO$_3$ film. In addition, several researchers observed spin-dependent excitation around 2 eV in doped and nondoped manganites by means of the resonant inelastic x-ray scattering experiments.

In this paper, we have investigated electronic structure as well as the photoinduced effect of LaMnO$_3$ film. We observed temperature-dependent absorption bands at $\approx 1.6$ eV and $\approx 3$ eV. We further observed that the photoexcitation of the down-spin $d$ electrons significantly suppresses (enhances) the lower-lying (higher-lying) $d$-$d$ band, and ascribed the behavior to the photoinduced disorder of the Mn$^{3+}$ spins.

A LaMnO$_3$ film was fabricated using a laser molecular-beam epitaxy method on a SrTiO$_3$ (100) substrate. Details of the synthesis process were described elsewhere. An x-ray diffraction measurement revealed that the obtained films were oriented in the pseudo-tetragonal setting. That is, the ferromagnetic $ab$ plane is parallel to the film surface. The Néel temperature $T_N(\approx 60$ K) was determined from the inflection point of the temperature dependence of the magnetization $M$, which was measured at 0.1 T after cooling down to 5 K in the zero field. The absorption coefficient $\alpha(\omega)$ was determined from transmission spectra using the standard formula neglecting the multi-reflection effect. The film thickness was 1790 Å. The transmission spectra were measured with a grating-type spectrometer. Reflectance correction is not performed, since the reflectivity ($R \approx 0.15$) is low and nearly constant in the spectral region investigated (0.6–3.1 eV). Here, note that the spectral region is limited by absorption of the SrTiO$_3$ substrate.
components by Gaussians, that is, shows a prototypical example of the absorption spectra at 4K.

We used a nanosecond optical parametric oscillator system pumped by a yttrium-aluminum-garnet (YAG) laser (355 nm, 10 Hz) as an excitation source. The pulse width was 3–5 ns. We confirmed that the SrTiO3 (100) substrate does not show any photoinduced signal, when the excitation photon energy was set below the absorption edge (=3.1 eV) of the SrTiO3 substrate. In the time-resolved spectroscopy, a xenon flush lamp was synchronized with the YAG laser. The transmitted light was detected with a gated charge-coupled device camera attached at the output stage of a grating monochromator. We put a polarizer in front of the monochromator to eliminate the intense scattering from the excitation light. The time resolution of the system was 12 ns. In order to obtain the overall temporal behavior of the photoinduced absorption change, we used continuous wave lasers, i.e., He-Ne laser (1.95 eV) and He-Cd laser (2.81 eV), as probe light sources. The intensities $I(t)$ of the transmitted light were detected with a P-intrinsic-N photodiode, and its temporal behavior was accumulated with a digital oscilloscope.

We first carefully investigated the temperature dependence of the absorption spectra of the LaMnO3 film. Figure 1 shows a prototypical example of the absorption spectra at (a) 4K ($\ll T_N$) and at (b) 300 K ($\gg T_N$). Consistent with the work done by Quijada et al., we observed a characteristic transfer of the spectral weight from the ultraviolet region to the visible region. Figure 1(c) shows temperature differential spectrum of the LaMnO3 film, which shows negative (positive) component at $\approx 1.6$ eV and $\approx 3.0$ eV, even though the spectral region was limited below 3.1 eV. For convenience of explanation, we will call the lower-lying (higher-lying) component $S_{\text{up}}$ ($S_{\text{down}}$). The peak position $\hbar \omega_0$ and the full width at half maximum $\Gamma$ of the $S_{\text{up}}$ component show negligible temperature-dependence. So, we expressed the two components by Gaussians, that is, $\propto \exp\left[-4 \ln 2 \left(\frac{\hbar \omega - \hbar \omega_0}{\Gamma}\right)^2\right]$.

FIG. 1. Absorption spectra of LaMnO3 film at (a) 4 K and at (b) 300 K. Thin solid curves represent the d-d transitions, while thin broken curves represent the charge-transfer (CT) transition. $S_{\text{up}}$ ($S_{\text{down}}$) stands for the d-d transition into the adjacent Mn$^{3+}$ site with the parallel (antiparallel) spin. The bottom figure (c) represents temperature differential spectrum ($\Delta \alpha = \alpha_{300K} - \alpha_{4K}$).

where $\hbar \omega_0$ and $\Gamma$ are the fixed values: $\hbar \omega_0=1.62$ eV (3.5 eV) and $\Gamma=0.79$ eV (0.70 eV) for the $S_{\text{up}}$ ($S_{\text{down}}$) component. Keeping these two components in mind, we decomposed the overall spectra into two temperature-dependent components (thin solid curves in Fig. 1) and three temperature-independent components (thin broken curves). The positions of the latter three components were chosen at $\hbar \omega_0=1.47$, 2.44, and 4.5 eV so as to cover the spectra. The residual parameters, $\Gamma$ and the spectral weight $S$, are adjusted so that the sum of the Gaussians reproduce the temperature-dependent component except around $\approx 1.6$ eV and $\approx 3$ eV: $\Gamma=1.20$ eV and $S=1.22 \times 10^5$ eV cm$^{-1}$ for the 1.47 eV component, $\Gamma=0.93$ eV and $S=0.72 \times 10^5$ eV cm$^{-1}$ for the 2.44 eV component, and $\Gamma=1.93$ eV and $S=1.08 \times 10^5$ eV cm$^{-1}$ for the 4.5 eV component. The temperature variation of the spectra can be reproduced only by the spectral weights of the $S_{\text{up}}$ and $S_{\text{down}}$ components.

In Fig. 2, we plotted the spectral weights of the $S_{\text{up}}$ component (open circles) and the $S_{\text{down}}$ component (filled circles). As temperature increases beyond $T_N$, the spectral weight of the $S_{\text{up}}$ component gradually transfers to the $S_{\text{down}}$ component. These temperature dependencies are well explained if we ascribe the $S_{\text{up}}$ ($S_{\text{down}}$) component to the d-d transition into the adjacent Mn$^{3+}$ site with the parallel (antiparallel) spin. With increases of temperature above $T_N$, the probability of finding a parallel (antiparallel) spin pair within the $ab$ plane decreases (increases), and eventually becomes the same ($=\frac{1}{2}$) in the paramagnetic phase. The rather gradual spectral weight transfer above $T_N$ may be ascribed to the residual short-range ferromagnetic correlation. Here, we roughly estimated the oscillator strength $f_{\text{dd}}$ of the d-d transition from the spectral weight of the $S_{\text{up}}$ component.

The magnitude of $f_{\text{dd}}=0.04/\epsilon_{\text{g}}$ electron is comparable with that ($f_{\text{dd}}=0.05/\epsilon_{\text{g}}$) of the ferromagnetic Sm$_{0.25}$Sr$_{0.75}$MnO$_3$ film.

FIG. 2. Spectral weight of the $S_{\text{up}}$ component and the $S_{\text{down}}$ component of LaMnO3 film. $T_N$ stands for the Néel temperature.

Figure 3(a) shows the differential absorption spectra $\Delta \alpha$ soon after the photoexcitation at 1.5 eV (gray spectrum) and at 2.3 eV (black spectrum). In both spectra, negative (positive) signal is observed at $\approx 1.6$ eV (at $\approx 3$ eV), which is close to the $S_{\text{up}}$ ($S_{\text{down}}$) component. So, we concluded that the photoexcitation modifies the spectral weights of the d-d tran-
sitions. The magnitude of the photoinduced spectral change is proportional to $I$ up to $I=4$ mJ/cm$^2$. We further estimated the quantum efficiency $\Phi$ for the $S_{\text{up}}$ component and plotted them in Fig. 3(b), taking account of the reflectivity and transmittance at $E_{\text{pump}}$. Magnitude of $\Phi$ is nearly constant ($\sim 3$ site/photon) below 2 eV, but jumps to $\sim 8$ site/photon when $E_{\text{pump}}$ exceeds $\sim 2$ eV. This observation excludes the conventional heating effects as the origin for the photoinduced spectral change.

Matsuda et al.\textsuperscript{3} reported a similar excitation photon energy dependence in the photoinduced absorption at the $J$-gap transition ($\sim 3$ eV) in a ferromagnetic (Nd,Sm)$_{0.6}$Sr$_{0.4}$MnO$_3$ film. In this system, the profile of $\Delta \alpha$ is analogous to the spectral change between the ferromagnetic and paramagnetic phases. In addition, the photoinduced signal disappears in the spin-disordered paramagnetic phase. Based on these observations, they concluded that the observed photoinduced effect is originated in the photoinduced spin disorder, which is much enhanced by the excitation of the down-spin $d$ electrons. We think that the presently observed photoinduced effect is also ascribed to photoinduced disorder of the Mn$^{3+}$ spins, because the enhancement of $\Phi$ [Fig. 3(b)] appears to correlate with the CT excitation of the down-spin $d$ electrons. In addition, the photoinduced spectral change [Fig. 3(a)] was analogous to the spectral change [Fig. 1(c)] between the spin-ordered and spin-disordered phases.

Finally, let us discuss temperature dependence of the photoinduced signal. Figure 4(a) shows prototypical examples of temporal behavior of $\frac{\Delta T}{T}$ at $E_{\text{probe}}=1.95$ eV, which is equivalent to $10$ meV, where $I_o$ represent the intensity of the transmitted light without photoexcitation. Base on the above interpretation, the magnitude of $\frac{\Delta T}{T}$ is equivalent to the degree of photoinduced spin disorder. The $\frac{\Delta T}{T}$ curves are well reproduced by the single exponential function: $\Delta T/T = A \cdot \exp(-t/\tau) + C$, where $A$ and $\tau$ are the amplitude and the lifetime, respectively. The constant term ($C$) is probably due to the heating effect, lasting for much longer time than the time range concerned here. Open circles in Fig. 4(b) represent $A$ and $\tau$ for the $S_{\text{up}}$ component. Magnitude of $A$ is nearly constant below $T_N$, but gradually decreases as temperature increases beyond $T_N$. On the other hand, $\tau$ is almost temperature-independent even near $T_N$. This is in sharp contrast with the La$_{0.7}$Ca$_{0.3}$MnO$_3$ film,\textsuperscript{4} in which $\tau$ critically slows down on approaching the Curie temperature $T_C$. Similar behaviors of $A$ and $\tau$ are observed for the $S_{\text{down}}$ component (indicated by filled circles), though the data points are rather scattered. These observations suggest that the local spin correlation does not change much even around $T_N$. Actually, Hirota et al.\textsuperscript{33} observed ferromagnetic spin-wave-like dispersion for $E \approx 10$ meV even near $T_N$, indicating residual short-range ferromagnetic spin correlation due to two-dimensional exchange coupling. Here, note that the optical probe mainly detects the nearest-neighboring spin correlation. Then, it is plausible that the optical probe does not feel the long-range antiferromagnetic-paramagnetic phase transition of LaMnO$_3$.

In summary, we have investigated the electronic structure as well as the photoinduced effect in an antiferromagnetic LaMnO$_3$ film. We decomposed the absorption spectra into three spin-independent CT components and two spin-dependent $d$-$d$ components, and concluded that the charge gap has the CT character. We further observed that the photosexcitation significantly influences the spin-dependent $d$-$d$ components due to the photoinduced disorder of the Mn$^{3+}$ spins.

Temperature dependence of the photoinduced signal of LaMnO$_3$ is qualitatively different from that of the ferromagnetic La$_{0.7}$Ca$_{0.3}$MnO$_3$.

29. $T_N$ of our LaMnO$_3$ film is lower than that (≈140 K) of the LaMnO$_3$ bulk. This may be due to the slight oxygen deficiency, because the film was synthesized in a moderate oxidizing atmosphere in order to avoid the cation deficiencies.
30. The temperature change of the absolute reflectivity was less than 1.5% in the spectral range of 0.7–3.0 eV. The resultant error in the absorption coefficient $\alpha$ is $\pm 0.01 \times 10^5$ cm$^{-1}$, which is much smaller than $\alpha$ and $\Delta \alpha$ (see Fig. 1).
31. The absolute magnitude of $S_{\text{down}}$ has ambiguity due to the limitation of the spectral range.
32. The refractive index $n$ of LaMnO$_3$ is $\sim 2$ in the visible region.
