(Received 10 April 2003; published 23 October 2003)

The isolated negatively charged silicon vacancy ($V_{Si}^-$) in the hexagonal lattices of 4H- and 6H-SiC has been studied by electron paramagnetic resonance (EPR). The local structure was suggested to have $T_d$ symmetry from the isotropic g value within the resolution of the conventional X-band measurements, from the isotropic $^{29}$Si hyperfine interaction of the next-nearest-neighbor silicon atoms and from the absence of the zero-field splitting with the high spin state of $S=3/2$. From the $^{13}$C hyperfine spectrum of the nearest-neighbor carbon atoms, the two kinds of $V_{Si}^-$, denoted $V_{Si}^-(I)$ and $V_{Si}^-(II)$, respectively, have been distinguished. $V_{Si}^-(I)$ and $V_{Si}^-(II)$ are assigned to be arising from hexagonal site ($h$) and quasicubic sites ($k = k_1$ and $k_2$ in 6H-SiC), respectively. In both $V_{Si}^-(I)$ and $V_{Si}^-(II)$, from the $^{13}$C hyperfine interactions, the symmetry has been revealed to be $C_{3v}$ with the arrangement of the four nearest-neighbor carbon atoms slightly distorted from a regular tetrahedron.

I. INTRODUCTION

The isolated lattice vacancy is one of the most fundamental intrinsic defects in semiconductor crystals. In the structure determination at the atomic level, for which electron paramagnetic resonance (EPR) is the principal experimental tool, a sufficient concentration of vacancies is produced as radiation damages by irradiation with high energy electrons. The vacancy usually introduces electrical levels into the forbidden gap, and can exist in different charge states. The charge state determined by the number of electrons trapped in the vacancy can be varied by the position of the Fermi level which is controlled by the kind and the concentration of major impurities and by the dose of the electron irradiation.

The important factors which govern the geometric and electronic structures of vacancies are the degree of the lattice structure relaxation attainable and the electron-electron interaction. Thus, even among the isoelectronic vacancies, different symmetries and different spin states emerge in different semiconductor crystals due to the difference in both the strength of the bonding and the degree of the delocalization of the wave function. An interesting example is the wave function along the [110] chain was confirmed by electron nuclear double resonance (ENDOR) measurements.3 On the other hand, $V^-\,^-$ in diamond has $T_d$ symmetry with a high spin ground state ($S = 3/2$).3 The conservation of the $T_d$ symmetry with the high spin ground state of $S=3/2$ is understood from the simple model of defect molecular orbitals, which are linear combinations of the dangling bond orbitals of four atoms around the vacancy. Under the $T_d$ symmetry, the defect molecular orbitals split into an $a_1g$ singlet and a $t_2g$ triplet.4 With five electrons, the electronic configuration of the ground state is $a_1^4t_2^1$. With the three unpaired electrons occupying each of three different orbitals of the threefold degenerate $t_2$ state, the repulsion among the highly localized three electrons is minimized by allowing the electrons to stay far apart. The ground state is the orbitally nondegenerate $A_2$ state which is not subject to a Jahn-Teller distortion. The negatively charged silicon vacancy ($V_{Si}^-$) in 3C-SiC ($T_d^2$, $E_g = 2.40$ eV) (Ref. 5) and the neutral Ga vacancy ($V_{Ga}^0$) in GaP ($T_d^2$, $E_g = 2.26$ eV) (Refs. 6 and 7) were also determined to have $T_d$ symmetry.

For $V_{Si}^-$ in the hexagonal lattices of 4H-SiC ($C_{6v}$, $E_g = 3.28$ eV) and 6H-SiC ($C_{4v}$, $E_g = 3.10$ eV), from the EPR spectra which have isotropic g values and do not exhibit zero-field splitting (ZFS), the deviation from the regular tetrahedron has not been revealed by the conventional X-band EPR measurements.8,9 In the $T_d$ symmetry, all three $\Delta M_S = \pm 1$ transitions of $S=3/2$ are superimposed since the ZFS vanishes.10,11 The effective spin of $S=3/2$ was determined by the $^{29}$Si (I = 1/2, natural abundance 4.68%) ENDOR measurement of the next-nearest-neighbor (NNN) silicon atoms since the ENDOR frequencies $h\nu = |M_{S=3/2}\cdot g_B\cdot B|$ do depend on the effective spin $S$.12 The high spin state was ascribed to an electronic configuration of $a_1^2t_2^2$ of $T_d$ symmetry. Furthermore, theoretical studies also supported the stability of the high spin state ($S=3/2$) and the $T_d$ symmetry.8,12

We have recently demonstrated in the $T_{22a}$ center in n-type 4H-SiC (n-4H-SiC) that the high spin state of $S = 3/2$ is also realized in a negatively charged silicon vacancy having $C_{3v}$ symmetry.13 The EPR spectrum of $T_{22a}$ does exhibit a fine structure although the ZFS is small ($|D$
The concentration of the carbon atoms is slightly distorted from a regular tetrahedron. Silicon vacancy and revealed that the arrangement of the NN atoms is expected from the symmetry-lowering crystal field alone. The orbitally nondegenerate $^4A_2$ which is not subject to a Jahn-Teller distortion is derived from the configurations $a_1^2e^2$ and $e^2a_1^2$.

A small deviation from an ideal tetrahedron in the atomic arrangements of the SiC$_4$ tetrahedron in 4H- and 6H-SiC was revealed from the high-resolution x-ray structure determination. The example of the $T_{\text{d}}$ center indicates that the spin quartet state of $V_{\text{Si}}$ in the hexagonal polytypes might not necessarily require the $T_{\text{d}}$ symmetry. In our present work, we have measured the angular dependence of the $^{13}$C (I=1/2, natural abundance 1.1%) hyperfine lines of the four NN atoms of $V_{\text{Si}}$ in 4H-SiC and in 6H-SiC, since the $^{13}$C hyperfine interactions are most crucial in a structural determination of the silicon vacancy. Wimbauer et al. reported the $^{13}$C hyperfine splittings of the NN atoms of $V_{\text{Si}}$ in 4H-SiC when the magnetic field is parallel to the c axis ([0001] axis). They measured the angular dependence of the $^{13}$C hyperfine lines of a NN atom which is located along [0001] (to be denoted the axial carbon atom); however, the angular dependence of the $^{13}$C hyperfine lines of the three NN atoms in the basal plane (to be denoted basal carbon atoms) was not reported. We have revealed that the symmetry of $V_{\text{Si}}$ in both 4H-SiC and 6H-SiC is indeed $C_{3v}$ from the detailed measurements of the $^{13}$C hyperfine interaction of the NN atoms.

SiC has many polytypes differing in the stacking sequence of Si-C bilayers. Technologically important polytypes are 3C-, 4H-, and 6H-SiC. In the cubic lattice of 3C-SiC, each silicon and carbon has one site. In performing a detailed local structure determination of defects and impurities in the hexagonal (nH-)SiC crystals, we need to consider that there are $n/2$ inequivalent sites for each silicon and carbon sublattice. In 4H-SiC, each silicon and carbon has two inequivalent sites with either a hexagonal (h) or quasicubic (k) character as shown in Fig. 1(a). In 6H-SiC, each silicon and carbon has one hexagonal (h) site and two quasicubic ($k_1$ and $k_2$) sites, as shown in Fig. 1(b). The identification of impurities at the inequivalent lattice sites is important because the properties, such as their energy levels in the band gap or the efficiency of doping, usually depend on the site which they occupy. EPR spectra at inequivalent sites in nH-SiC have been distinguished for impurities such as group-III atoms, group-V atoms, and transition metal ions.

In the hexagonal (nH-)SiC crystals, it is expected that there should be $n/2$ kinds of silicon vacancies corresponding to $n/2$ inequivalent sites of silicon. Recently, two EPR spectra arising from $V_{\text{Si}}^{-}$ in 4H-SiC were resolved at the W band (95 GHz) by the difference in the g value. One with the isotropic g value of $g(k)=2.0032$ was assigned to be $V_{\text{Si}}^{-}$ at the quasicubic site and the other with a slightly anisotropic g value with $g_{\perp}(h)=g(k)-0.00044$ and $g_{\parallel}(h)=g(k)-0.00022$ was assigned to be $V_{\text{Si}}^{-}$ at the hexagonal site. In the X band (9.5 GHz) EPR spectra of $V_{\text{Si}}^{-}$ in n-4H-SiC and n-6H-SiC, the primary lines and the $2^{9}\text{Si}$ hyperfine lines of NNN atoms are not sufficient to resolve the vacancies at different sites of silicon. In our present work, from the $^{13}$C hyperfine spectrum of the NN atoms, the two kinds of $V_{\text{Si}}^{-}$, denoted $V_{\text{Si}}^{-}(\text{I})$ and $V_{\text{Si}}^{-}(\text{II})$, respectively have been distinguished. It will be shown that $V_{\text{Si}}^{-}(\text{I})$ is arising from $V_{\text{Si}}^{-}$ at

II. EXPERIMENT

The samples used in our experiments were single crystaline n-type 4H- and 6H-SiC (Nippon Steel: nitrogen dopant) with the carrier concentrations of $1 \times 10^{17}/\text{cm}^2$. The sample whose thickness is 1.5 mm was cut into the appropriate size (3 mm $\times$ 15 mm) for our EPR measurements in the X band. The crystals of 4H- and 6H-SiC were irradiated by 3-MeV electrons with total fluencies of $4 \times 10^{18} \text{e/cm}^2$ and $1 \times 10^{19} \text{e/cm}^2$, respectively. The sample was placed on a water-cooled holder and was kept below 330 K during the electron irradiation. The samples of 4H-SiC were annealed at 573 K by a muffle furnace so as to decrease the interference with the unidentified signals. The line positions of the continuous wave (cw) EPR spectra were measured at room temperature on a Bruker Elexsys E500 X-band spectrometer by using the amplitude of 100-kHz field modulation of 0.01 mT. The $^{13}\text{C}$ hyperfine lines of $V^\perp_{Si}$ in 4H-SiC were measured with the microwave power of 0.2 $\mu$W by using the spherical cavity (Bruker ER4122SHQ, $Q_L = 8600$, $TE_{011}$ mode). The $^{13}\text{C}$ hyperfine lines of $V^\perp_{Si}$ in 6H-SiC were measured with the microwave power of 2 $\mu$W by using the optical transmission cavity (Bruker ER4104OR, $Q_L = 4000$, $TE_{102}$ mode). The calibration of the magnetic field was carried out by measuring simultaneously at room temperature the sample and the perylene cation in conc. H$_2$SO$_4$ ($g = 2.002569 \pm 0.000006$) (Refs. 26 and 27) sealed in the capillary which was co-mounted with the sample. In estimating the spin concentration of $V^\perp_{Si}$, the signal intensity obtained by double integration of the first derivative signal was compared with that of the EPR signal of Cr$^{3+}$ in a single crystal of ruby$^{28}$ co-mounted with the sample. The relative intensity ratio between the $^{13}\text{C}$ hyperfine line and the primary line was estimated by using the signal intensities obtained by (peak height) $\times (\Delta B_{pp})^2$. In measuring the line width, the modulation amplitude of 0.008 mT was used.

III. RESULTS AND DISCUSSION

A. Angular dependence of $^{13}\text{C}$ hyperfine lines

In conventional X-band EPR measurements of $V^\perp_{Si}$ of 4H-SiC and 6H-SiC, from the primary lines with the isotropic $g$ value and from the absence of the ZFS although with $S = 3/2$, the deviation from an ideal tetrahedron in the arrangement of the four carbon atoms around the silicon vacancy has not been observed. We have measured the angular dependence of the $^{13}\text{C}$ hyperfine lines of nearest-neighbor carbon atoms in the X-band EPR spectra in a high resolution condition by using small amplitude (0.01 mT) of 100-kHz field modulation.

Here, we describe the features of angular dependence of the $^{13}\text{C}$ hyperfine lines expected for the two cases in which the local arrangement of the four carbon atoms around the silicon vacancy has $T_d$ and $C_{3v}$ symmetries, respectively. As illustrated in Fig. 1, in the two magnetically distinguishable orientations of a tetrahedron consisting of four carbon atoms around the silicon vacancy, there are altogether eight carbon atoms, two axial carbon atoms labeled C1 and C1', and six basal carbon atoms labeled C2-C4 and C2'-C4'.

With $B_{pp}[[001]]$, for both $T_d$ and $C_{3v}$ symmetry, two sets of the $^{13}\text{C}$ hyperfine lines with the intensity ratio 1:3 corresponding to the axial and the basal carbon atoms are expected. For both $T_d$ and $C_{3v}$ symmetries, the $^{13}\text{C}$ hyperfine matrix ($A^{^{13}\text{C}}$) of the axial carbon atoms is uniaxial around [0001], with the maximum hyperfine splitting at $B_{pp}[[001]]$ and with the minimum at $B_{pp}[[1100]]$. Since two axial carbon atoms C1 and C1' are not magnetically distinguishable, the hyperfine line arising from the two axial carbon atoms does not split upon rotation. For both $T_d$ and $C_{3v}$ symmetries, the six basal carbon atoms are symmetry related. In the rotation with $B_{pp}[[1100]]$, the $^{13}\text{C}$ hyperfine line of the basal carbon atoms splits into, at most, three lines with the intensity ratio 1:1:1. Upon rotation with $B_{pp}[[1120]]$, the $^{13}\text{C}$ hyperfine line of the basal carbon atoms splits into four lines with an intensity ratio 1:2:2:1 at an arbitrary rotation. These patterns of the rotational plots of the line positions of the basal carbon atoms are similar whether the local arrangement of each of two sets of four carbon atoms C1–C4 and C1'–C4' is an ideal tetrahedron or a slightly distorted tetrahedron with $C_{3v}$ symmetry. In $C_{3v}$ symmetry, the axial carbon atoms and the basal carbon atoms are not symmetry related, it is expected that the principal values of $A^{^{13}\text{C}}$ should be different between the axial and basal carbon atoms. In the $C_{3v}$ symmetry, the $A^{^{13}\text{C}}$ of the basal carbon atoms is nearly uniaxial. The principal axis with the largest principal value is, herein, termed the unique axis. In the $C_{3v}$ symmetry, the unique axis is in a (1120) plane. An orientation which exhibits the maximum hyperfine splitting with the unique axis parallel to $B_0$ is included in the rotation with $B_{pp}[[1120]]$. The minimum hyperfine splitting of the basal carbon atoms occurs either with $B_0$ perpendicular to the unique axis in a (1120) plane or with $B_{pp}[[1120]]$. In the pattern of the rotational plots of the line positions, it is expected that the $C_{3v}$ symmetry should be revealed by the difference in both the maximum hyperfine splitting and the minimum hyperfine splitting between the axial and the basal carbon atoms. The deviation from an ideal tetrahedron might be also evidenced by the deviation of the angle between the unique axis of $A^{^{13}\text{C}}$ of the basal atoms and the $c$ axis ([0001]) from an ideal tetrahedral angle.

1. 4H-SiC

The EPR spectrum of the electron irradiated n-4H-SiC when the magnetic field is parallel to the $c$ axis ($B_0[[001]]$) is shown in Fig. 2. In the central part of the spectrum, the strong primary line labeled $a$ with the linewidth $\Delta B_{pp} = 0.022 \text{mT}$ of $V^\perp_{Si}$ ($g = 2.0028$) (Ref. 13) is observed. The satellite lines labeled $b$ and $c$ arise from $^{29}\text{Si}$ ($I = 1/2$, natural abundance 4.6832%) hyperfine interactions of NNN atoms,$^{29}$ the $b$ lines from the configurations with one $^{28}\text{Si}$ nucleus in 12 silicon atoms of the NNN shell, and the $c$ lines from the configurations with two $^{29}\text{Si}$ nuclei in the NNN shell. The hyperfine splitting of 0.298 mT agrees with that was
reported.\(^8\) The relative intensity ratios of \(b/a\) and \(c/a\), 0.252 and 0.038, respectively, agree with those ~0.273 and 0.037, respectively calculated from the natural abundance of silicon isotopes.\(^{13}\) The spin concentration of \(V_{\text{Si}}\) was estimated to be \(5 \times 10^{17}/\text{cm}^3\).

The \(^{13}\text{C}\) hyperfine spectrum of the axial and the basal carbon atoms at \(B_\|\|[0001]\) was reported by Wimbauer et al.\(^8\) In our spectrum shown in Fig. 2, the \(d\) and \(e\) lines correspond to the \(^{13}\text{C}\) hyperfine lines from basal carbon atoms and axial carbon atoms, respectively. In our spectrum taken with a high resolution, we note that the \(d\) lines consist of two sets of lines labeled \(d_1\) and \(d_2\). Thus, we could resolve two kinds of \(V_{\text{Si}}\), to be denoted \(V_{\text{Si}}(\text{I})\) and \(V_{\text{Si}}(\text{II})\), respectively. At some orientations where the interfering signals did not overlap, it is noticeable that these \(^{13}\text{C}\) hyperfine lines accompany weak satellite lines arising from the configurations with one \(^{13}\text{C}\) atom in the NN shell and one \(^{29}\text{Si}\) atom in the NNN shell, at the line positions of the same hyperfine splitting ~0.298 mT and with the same relative intensity ratio \((b/a)\) as the primary line \(a\). In the spectrum shown in Fig. 2, the satellite lines accompanied with the low field \(e\) line are labeled \(e'\).

Upon rotation with \(B_\|\|[1\overline{1}00]\), each of \(d_1\) and \(d_2\) lines at \(\mathbf{B}_\|\|[0001]\) splits into three lines with the intensity ratio 1:1:1. (labeled \(f_1\), \(g_1\), and \(h_1\) for the three lines from \(d_1\), and \(f_\|\), \(g_\|\), and \(h_\|\) for the three lines from \(d_2\), respectively). In the spectrum with the rotation angle 75° from \([0001]\) shown in Fig. 3, the low field components of the satellite lines (labeled \(f'_1\) and \(f'\), respectively) corresponding to \(b\) lines of the primary line \(a\) are noticed in both \(f_1\) and \(f_\|\) lines. This orientation is a typical example that has been used to estimate

---

**FIG. 2.** The EPR spectrum of the electron-irradiated \(n\)-type \(4H\)-SiC taken with the magnetic field along the \([0001]\) axis at room temperature. The microwave frequency, the microwave power, and the amplitude of the 100-kHz field modulation were 9.457 GHz, 0.2 \(\mu\text{W}\), and 0.01 mT, respectively. The lower spectrum is the expanded spectrum.

**FIG. 3.** The EPR spectrum of the electron-irradiated \(n\)-type \(4H\)-SiC taken with the magnetic field direction \((\theta=75^\circ, \varphi=90^\circ)\) at room temperature. The microwave frequency, the microwave power, and the amplitude of the 100-kHz field modulation were 9.457 GHz, 0.2 \(\mu\text{W}\), and 0.01 mT, respectively. The lower spectrum is the expanded spectrum.

**FIG. 4.** The EPR spectrum of the electron-irradiated \(n\)-type \(4H\)-SiC taken with the magnetic field perpendicular to \([0001]\) at room temperature. (a) The spectrum taken with \(\mathbf{B}_\|\|[1\overline{1}20]\). (b) The expanded spectrum of (a). (c) The spectrum taken with \(\mathbf{B}_\|\|[1\overline{1}00]\). (d) The expanded spectrum of (c).
FIG. 5. Angular dependence of the line positions of $V_{Si}$ in 4H-SiC. The crystal was rotated with the magnetic field in the (1100) plane. In the magnetic field direction ($\theta, \phi=90^\circ$, $\theta=0^\circ$ for $B_\|([0001]$ and $\theta=90^\circ$ for $B_\|[11\overline{2}0]$. See the text for the marks representing the line positions observed.

The angular dependence of the line positions of $^{13}$C hyperfine lines measured upon rotation with $B_\|[1\overline{1}20]$ is shown in Fig. 5. The angular dependence of the line positions of $^{13}$C hyperfine lines upon rotation with $B_\|[11\overline{2}0]$ is shown in Fig. 6. In Figs. 5 and 6, each of the points marked with filled triangles (the primary line), open squares [the $^{13}$C hyperfine line of axial carbon atoms of $V_{Si}(I)$], filled squares [the $^{13}$C hyperfine line of axial carbon atoms of $V_{Si}(II)$], open circle [the $^{13}$C hyperfine line of basal carbon atoms of $V_{Si}(I)$], and filled circles [the $^{13}$C hyperfine line of basal carbon atoms of $V_{Si}(II)$] represents an EPR line position observed in the spectra.

The plots of the line positions upon the rotation with $B_\|[11\overline{2}0]$ shown in Fig. 6 indicate that the maximum hyperfine splitting of the basal carbon atoms observed at the unique axis direction is slightly smaller than that of the axial carbon atoms. Furthermore, when $B_\|[11\overline{2}0]$ at which the axial carbon atoms labeled $e$ exhibit the minimum hyperfine splitting and the basal carbon atoms labeled $g$ exhibit the minimum one of the rotation with $B_\|[1\overline{1}00]$, their line positions do not superimpose (Fig. 5). Both the number of equivalent carbon atoms at special orientations and the pattern of the roadmap obtained by the angular dependence of the line positions indicate that both $V_{Si}(I)$ and $V_{Si}(II)$ do have $C_{3v}$ symmetry.

The signal intensity ratios of the axial (the $e$ line at $B_\|[0001]$) and the basal (the $d_I$ and $d_{II}$ lines at $B_\|[0001]$) $^{13}$C hyperfine lines with respect to the primary line ($a$) are shown in Table I. The values listed as the observed ratios were obtained as the average among the ratios measured at several orientations where the $^{13}$C hyperfine lines were relatively free from the interference of the unidentified signals.

2. 6H-SiC

The EPR spectrum of $V_{Si}$ in the electron irradiated $n$-type 6H-SiC when the magnetic field is parallel to the $c$ axis ($B_\|[0001]$) is shown in Fig. 7. The spin concentration of $V_{Si}$ was estimated to be $1 \times 10^{18}/cm^3$. In the central part of the spectrum, the strong primary line labeled $a$ (the linewidth $\Delta B_{pp}=0.030$ mT) accompanied with the characteristic satellite lines labeled $b$ and $c$ arising from the $^{29}$Si hyperfine interactions of NNN atoms is observed. The $g$ value was determined to be $2.0028\pm0.0001$, that is the same as that of $V_{Si}$ in 4H-SiC.
As for the $^{13}$C hyperfine lines of the NN carbon atoms, Schneider et al. reported the $c$ axis splitting for the axial and the basal carbon atoms. In Fig. 7, the $^{13}$C hyperfine lines arising from the axial carbon atoms are labeled $e$. Likewise, in $^{4}$H-SiC, the $^{13}$C hyperfine lines arising from the basal carbon atoms are resolved into two sets labeled $d_{I}$ and $d_{II}$, respectively. Thus, our high resolution $^{13}$C hyperfine spectra taken with the magnetic field modulation of 0.01 mT could distinguish two kinds of $V_{Si^{2}}$, to be denoted $V_{Si^{2}}(I)$ and $V_{Si^{2}}(II)$, respectively.

The EPR spectra were recorded at 2.5° intervals with the crystal rotated around $\beta_{[11\overline{2}0]}$, with $B_{0}$ in the (0001) plane. In the magnetic field direction ($\theta, \phi=90^\circ$), $\theta=0^\circ$ for $B_{0}$[0001] and $\theta=90^\circ$ for $B_{0}$[1120]. The filled triangles and the filled squares represent the resonant primary lines and the axial $^{13}$C hyperfine lines, respectively. The filled and open circles represent the $^{13}$C hyperfine lines of the basal carbon atoms of $V_{Si^{2}}(I)$ and those of $V_{Si^{2}}(II)$, respectively.

The EPR spectra were recorded at 2.5° intervals with the crystal rotated around [1100], with $B_{0}$[1100] at room temperature. The angular dependence of the line positions of the $^{13}$C hyperfine lines is shown in Fig. 8. Each point represents the line position observed. In the rotation with $B_{0}$[1100], each of $d_{I}$ and $d_{II}$ line at $B_{0}$[0001] splits into three lines at an arbitrary angle. In the rotation with $B_{0}$[1100], the $e$ line could not be resolved into two lines corresponding to $V_{Si^{2}}(I)$ and $V_{Si^{2}}(II)$. In obtaining the EPR parameters from the fitting of the line positions, we assumed that the $e_{I}$ and $e_{II}$ lines superimposed. The signal intensity ratios of the axial and the basal $^{13}$C hyperfine lines with respect to the primary line are included in Table I.

### B. EPR parameters

The spin Hamiltonian parameters were obtained by fitting observed field strengths and microwave frequencies to the spin Hamiltonian,

$$H_S = \beta_e \tilde{S} \cdot g \cdot B + \tilde{S} \cdot D \cdot S + \tilde{S} \cdot A_{13C} I - g_{13C} \beta_e I \cdot B,$$

(1)
where electron spin \( S = 3/2 \) and \(^{13}\)C nuclear spin \( I = 1/2 \). \( \beta_n \)

is the Bohr magneton and \( \beta_n \) is the nuclear magneton. The nuclear Zeeman matrix was taken as isotropic (\( g\nu_{13C} = 1.40483 \)). \( g \), \( D \), and \( A \) denote the \( g \) matrix, the ZFS tensor, and the hyperfine matrix, respectively. The ZFS matrix \( D \) was set to zero matrix \( O \). The least squares fitting was carried out by using computer program EPRFOR in which the resonant magnetic fields are calculated by the exact diagonalization of the spin Hamiltonian matrix. The spin Hamiltonian parameters were obtained by using a crystal coordinate system in which the \( z \) axis is [0001] and the \( x \) axis is [1100].

It should be noted that one rotation with \( B_0 \) in the (1100) plane or in the (1120) plane is sufficient to determine \( \Delta 13C \) of the axial carbon atom \( C1 \) when the symmetry of the vacancy belongs to the \( C_{3v} \) point group. In the case of the basal carbon atoms, \( \Delta 13C \) of \( C2 \) which is one particular basal carbon atom located on (1120) plane can be determined by applying the appropriate symmetry transformations to utilize the line positions of other carbon atoms as the line positions of \( C2 \) that should be obtained by the rotation in different planes. Thus, \( \Delta 13C \) of the basal carbon atom \( C2 \) can be determined from one rotation with \( B_0 \) in the (1100) plane or in the (1120) plane. By applying the appropriate symmetry transformations, the parameters belonging to other basal carbon atoms can be obtained. For obtaining \( \Delta 13C(\text{C}1) \) and \( \Delta 13C(\text{C}2) \) of both \( V\text{Si}(\text{I}) \) and \( V\text{Si}(\text{II}) \) in 4H-SiC, we used the line positions of both the rotation with \( B_0 \) in [1100] and that with \( B_0 \) in [1120]. For obtaining \( \Delta 13C(\text{C}1) \) and \( \Delta 13C(\text{C}2) \) of both \( V\text{Si}(\text{I}) \) and \( V\text{Si}(\text{II}) \) in 6H-SiC, we used the line positions of the rotation with \( B_0 \) in [1100]. For the least squares fitting, the line positions read from the spectra taken at every 2.5° were used.

The \( g \) matrix was obtained from the fitting of the primary lines. In both \( V\text{Si}(\text{I}) \) and \( V\text{Si}(\text{II}) \) in both 4H-SiC and 6H-SiC, the \( g \) matrix was isotropic within a relative accuracy of 0.0001. Recently, the difference in \( g \) value between \( V\text{Si} \) at the quasicubic site (\( g(k) = 2.0032 \), isotropic) and \( V\text{Si} \) at the hexagonal site (\( g(k) - g(h) = 0.00002 \)) in 4H-SiC was resolved by the measurement at the W band (95 GHz). The maximum difference in the line positions (\( g(k) - g(h) = 0.00004 \)) is estimated to be 0.0066 mT at the X band which is much smaller than the linewidth (\( \Delta B_{pp} = 0.022 \) mT at \( B_0 \) [0001]).

The EPR parameters obtained from the fitting of the line positions of 4H- and 6H-SiC are summarized in Table II. The root-mean-square (rms) error estimates for principal values and principal directions are included. The solid curves in Figs. 5, 6, and 8 are calculated by using the parameters obtained. In Table II, the number of measured line positions used and the rms field deviations (mT) achieved are listed for each fitting of the axial \( ^{13}C \) hyperfine lines of \( V\text{Si}(\text{I}) \), the basal \( ^{13}C \) hyperfine lines of \( V\text{Si}(\text{I}) \), the axial \( ^{13}C \) hyperfine lines of \( V\text{Si}(\text{II}) \), and the basal \( ^{13}C \) hyperfine lines of \( V\text{Si}(\text{II}) \).

In Table II, the reported values of \( \Delta 13C \) of \( V\text{Si}(\text{I}) \) in 4H-SiC (Ref. 8) are included. It should be noted that the averaged value (\( A^{13C}_1 = 80.1 \) MHz and \( A^{13C}_1 = 34.0 \) MHz) of \( \Delta 13C(\text{C}1) \) of \( V\text{Si}(\text{I}) \) and \( \Delta 13C(\text{C}1) \) of \( V\text{Si}(\text{II}) \) obtained in this work is in good agreement with the reported values (\( A^{13C}_1 = 80.1 \) MHz and \( A^{13C}_1 = 33.9 \) MHz).

### C. Structure and silicon sites of \( V\text{Si}^\text{l} \)

The wave function of the unpaired electron is described by a linear combination of atomic orbitals (LCAO) approximation

\[
\Psi = \sum_i \eta_i (\alpha_i \varphi_{nx} + \beta_i \varphi_{np}),
\]

where the summation is over the surrounding carbon (ns, np: 2s, 2p) and silicon (ns, np: 3s, 3p) atoms on which the unpaired electrons are delocalized. The fractional unpaired electron population (\( \eta_i^2 \)) on the atom concerned and the hybrid ratio (\( \beta_i^2/\alpha_i^2 \), where \( \alpha_i^2 + \beta_i^2 = 1 \)) are estimated from the hyperfine parameters. In the estimation (\( \eta_i^2 \alpha_i^2 \beta_i^2 = A_{iso} \), \( \eta_i^2 \beta_i^2 = A_{anis} \)), we used \( a_0 = 3776.92 \) MHz, and \( b_0 = 107.39 \) MHz for \( ^{13}C \).\(^{30,31} \)

The results are listed in Table III. In the wave function of the unpaired electron of \( V\text{Si}(\text{I}) \) of 4H-SiC, the fraction which localizes on the four NN carbon atoms is 63.4% and 63.6% for \( V\text{Si}(\text{I}) \) and \( V\text{Si}(\text{II}) \), respectively. In the wave function of the unpaired electron of \( V\text{Si}(\text{I}) \) of 6H-SiC, the fraction which localizes on the four NN carbon atoms is 63.6% and 65.1% for \( V\text{Si}(\text{I}) \) and \( V\text{Si}(\text{II}) \), respectively. As for the 12 NNN silicon atoms, the hyperfine splitting observed as the satellite lines of the primary line was isotropic within the resolution of our measurements and the anisotropic part which is arising from the contribution of 3p orbital could not be measured. In \( V\text{Si}(\text{II}) \) of both 4H-SiC and 6H-SiC, the sum of the contribution of the 3s orbital of 12 NNN silicon atoms is estimated to be 2.3% by using \( a_0 = -4594.12 \) MHz for \( ^{29}\text{Si} \).

From the pattern of the rotational plots, it is determined that both \( V\text{Si}(\text{I}) \) and \( V\text{Si}(\text{II}) \) in both 4H-SiC and 6H-SiC have a \( C_{3v} \) symmetry. With a \( C_{3v} \) symmetry, the axial carbon atom and basal carbon atom are not symmetry related. The deviation from an ideal tetrahedral symmetry is confirmed by the fact that, as seen from Table II, the principal values of \( \Delta 13C(\text{C}1) \) are not the same as the principal values of \( \Delta 13C(\text{C}2) \). From the small difference of the principal values of \( \Delta 13C \) between the axial carbon atoms and the basal carbon atoms, it is inferred that the distortion of the structure from \( T_d \) to \( C_{3v} \) is considered to be very small. The polar angle \( \theta \) of the unique axis of the \( ^{13}C \) hyperfine matrix of basal carbon atoms, 110.0°, 110.0°, 109.2°, and 109.1° for \( V\text{Si}(\text{I}) \) in 4H-SiC and in 6H-SiC and \( V\text{Si}(\text{II}) \) in 4H-SiC and in 6H-SiC, respectively, is deviated from an ideal tetrahedral angle (109.47°). The \( ^{13}C \) hyperfine spectra confirm that the NN atoms are four carbon atoms arranged in a configuration close to regular tetrahedron and that these carbon atoms have a relatively large spin density. We note that the contribution to the wave function of the unpaired electron from the atomic orbit of carbon is almost purely \( p \), as shown in Table III. The dominant structure relaxation in \( V\text{Si} \) is likely to be outward displacements of the NN atoms.
While the $C_{3v}$ symmetry is revealed by the $^{13}$C hyperfine interactions of the NN atoms, the ZFS has not been observed by conventional, cw EPR technique. By using the nutation method of pulsed EPR technique, the presence of ZFS in $V_{Si}$ in 4H-SiC was revealed.\textsuperscript{13} We showed that the primary line of $V_{Si}$ in 4H-SiC consists of all three $\Delta M_S=\pm 1$ transitions of $S=3/2$ of non-distorted configuration and $|S,M_S\rangle = |3/2, 1/2\rangle \leftrightarrow |3/2, -1/2\rangle$ transition of slightly distorted configuration. The nutation frequency of non-distorted configuration of which three $\Delta M_S=\pm 1$ transitions are superimposed or are located within the extent of the excitation bandwidth of the microwave pulse ($B_1 \sim 0.3$ mT) is $\omega_1 = g\beta g_1 h$. The nutation frequency of slightly distorted configuration is $2\omega_1$ since only $|3/2, 1/2\rangle \leftrightarrow |3/2, -1/2\rangle$ transition is excited by the microwave pulse with the $|3/2, \pm 3/2\rangle \leftrightarrow |3/2, \pm 1/2\rangle$ transitions being located away from the $|3/2, 1/2\rangle \leftrightarrow |3/2, -1/2\rangle$ transition by at least $\sim B_1$ due to the ZFS. In slightly distorted configuration, the $|3/2, \pm 3/2\rangle \leftrightarrow |3/2, \pm 1/2\rangle$ transitions which are likely to be broadened by a distribution of ZFS presumably due to local strains are too broad to be observed as separate signals. Thus, the magnitude of ZFS is distributed from a value smaller than $B_1$ to one larger than $B_1$. The criterion of whether configurations are nondistorted or distorted in the nutation experiments depends on the relative magnitude between $|D|$ and $B_1$.

In 4H-SiC, there are two types of silicon sites, one with

hexagonal character ($h$) and the other with cubic character ($k$), with the population ratio of 1:1. In $6H$-SiC, there are three types of silicon sites, one with a hexagonal character ($h$) and the other two with a cubic character ($k_1$, $k_2$), with the population ratio of 1:1:1. Now, we assign the $V_{Si}$ from $4H$-SiC and $6H$-SiC, the difference in the principal values between $^{13}$C(C1) and $^{13}$C(C2) is smaller in $V_{Si}$ (II) than in $V_{Si}$ (I). The polar angle $\theta$ of the unique axis of $^{13}$C(C2) is closer to tetrahedral angle (109.47°) in $V_{Si}$ (II) (109.2° in $4H$-SiC and 109.1° in $6H$-SiC) than in $V_{Si}$ (I) (110.0° in $4H$-SiC and 110.0° in $6H$-SiC). Thus, the deviation from an ideal tetrahedron is smaller in $V_{Si}$ (II) than in $V_{Si}$ (I). It is likely that the vacancy at the hexagonal silicon site should be more distorted than the vacancy at the quasicubic silicon site. As seen from Figs. 2–4, the concentration ratio $[V_{Si}$ (II)]/[V_{Si} (I)] in $4H$-SiC obtained from the intensity ratio between the corresponding $^{13}$C hyperfine lines ($d_{ul}/d_1$, $e_{ul}/e_1$, $f_{ul}/f_1$, $g_{ul}/g_1$, and $j_{ul}/j_1$) is $\sim$ 1.4. The concentration ratio $[V_{Si}$ (II)]/[V_{Si} (I)] in $6H$-SiC obtained from the intensity ratio between the corresponding $^{13}$C hyperfine lines of the basal carbon atoms ($d_{ul}/d_1$ in the case of the c axis spectrum shown in Fig. 7) is $\sim$ 3.0. Since the deviation from an ideal tetrahedron of $V_{Si}$ (I) is larger than that of $V_{Si}$ (II), and since the concentration ratio $[V_{Si}$ (II)]/[V_{Si} (I)] in $4H$-SiC is nearly twice as large as that in $6H$-SiC, we assume that $V_{Si}$ (I) and $V_{Si}$ (II) are vacancies at the hexagonal silicon site and at quasicubic site(s), respectively. In the case that the EPR spectra of impurities at all three different sites of $6H$-SiC are resolved, the difference of the EPR parameters between the hexagonal and quasicubic sites is much larger than that between two quasicubic sites.16–24 In our case of $V_{Si}$ in $6H$-SiC, the difference of the EPR parameters between the two quasicubic sites was too small to be resolved by cw EPR method.

In Table II, $^{13}$C of $V_{Si}$ in $3C$-SiC5 and $^{13}$C(C1) and $^{13}$C(C2) of $T_{V_{2a}}$ in $6H$-SiC (Ref. 13) are included. The $^{13}$C hyperfine matrix of the basal carbon atoms $^{13}$C(C2) of $V_{Si}$ (II) in $4H$- and $6H$-SiC is closer to that of $V_{Si}$ in $3C$-SiC than that of $V_{Si}$ (I) in $4H$- and $6H$-SiC. This fact supports the assignment that $V_{Si}$ (I) is at hexagonal silicon site and $V_{Si}$ (II) is at quasicubic site(s). The $^{13}$C hyperfine matrices of the axial carbon atoms $^{13}$C(C1) are similar among $V_{Si}$ in $3C$-SiC, $V_{Si}$ (I, II) in $4H$- SiC, $V_{Si}$ (I, II) in $6H$-SiC, and $T_{V_{2a}}$ in $4H$-SiC. From the similarity of $^{13}$C(C1) and $^{13}$C(C2) between $T_{V_{2a}}$ and $V_{Si}$ (I, II), the arrangement of four carbon atoms around the vacancy in $T_{V_{2a}}$ is similar to that of the isolated negatively charged vacancy $V_{Si}$ (I, II). Thus, the small ZFS of $T_{V_{2a}}$ is ascribed to additional symmetry-lowering crystal field caused by possible presence of an accompanying nonparamagnetic impurity or defect located at some distance along [0001].13

From the $^{13}$C hyperfine interaction of the NN carbon atoms, the symmetries of $V_{Si}$ (I) and $V_{Si}$ (II) both in $4H$-SiC and in $6H$-SiC are determined to be $C_{3v}$. Under $T_d$ symmetry, the high spin ground state $^{4}A_{2} (S=3/2)$ arises from electronic configuration $a_1^4f_2^1$. Under the $C_{3v}$ symmetry, the $t_2$ triplet splits into $a_1$ and a doublet $e$. The high spin ground state $^{4}A_2 (S=3/2)$ which is an orbitally non-degenerated state free from Jahn-Teller distortion is derived from the configurations $(a_1^4) e^2$ and $e^2 (a_1^4)$13,32 So far, the single vacancies which have $S=3/2$ ground state are limited to those having $T_d$ symmetry except $T_{V_{2a}}$ in $4H$-SiC.13 The lowering of the crystal field in $T_{V_{2a}}$ was ascribed to the possible presence of an impurity or defect at some distance along [0001]. In our present work, it is revealed that isolated vacancy $V_{Si}$ in the hexagonal lattices of $4H$-SiC and $6H$-SiC does have $S=3/2$ ground state although with $C_{3v}$ symmetry. Thus, threefold degenerate $t_2$ state under tetrahedral symmetry is not necessarily required to attain the high spin configuration of $S=3/2$. Our example in which three parallel spins are occupied in $a_1$ and $e$ under $C_{3v}$ symmetry demonstrates the important role of electron-electron interaction in determining the electronic state of vacancies of wide-gap semiconductor crystals such as SiC.

The intensity ratio of the $^{13}$C hyperfine line relative to the primary line listed in Table I is slightly smaller than that is calculated from the natural abundance of $^{13}$C. In $V_{Si}$ (I, II) in $4H$-SiC, the ratio $[V_{Si}$ (II)]/[V_{Si} (I)] obtained from the $^{13}$C hyperfine lines of the axial carbon atoms is slightly smaller than that obtained from the $^{13}$C hyperfine lines of the basal carbon atoms. The concentration ratio $[V_{Si}$ (II)]/[V_{Si} (I)] was obtained as the average among the peak height ratios at several orientations. For the axial carbon atoms of $V_{Si}$ (I, II) in $4H$-SiC, the number of orientations where the $^{13}$C hyperfine lines of $V_{Si}$ (I) and $V_{Si}$ (II) were resolved is limited. Since the signals from non-identified centers interfered with the weak $^{13}$C hyperfine lines at several orientations and moreover the splitting of the line positions between $V_{Si}$ (I) and $V_{Si}$ (II) is small, measuring the $^{13}$C hyperfine lines accurately was not easy. The fact that the ratio $[V_{Si}$ (II)]/[V_{Si} (I)] obtained from the $^{13}$C hyperfine lines of the basal carbon atoms in $4H$-SiC (1.4) is larger than that is calculated from the population ratio of silicon atoms between hexagonal and cubic sites (1.0) might suggest the difference in thermal stability between $V_{Si}$ (I) and $V_{Si}$ (II).

Even if the ZFS is vanishing, the high spin state might be detected by the splitting of hyperfine lines in the cw EPR measurements. From the second order perturbation treatment, the line position $B$ of the $[S,M_S=1,m_I] \leftrightarrow [S,M_S,m_I]$ transition is given as
Details of the coefficients in Eq. (3) are given in the Appendix. In the case of $S = 3/2$, it is expected that the hyperfine line should split into three lines. However, in our case, the maximum magnitude of the splitting is estimated to be 0.005 mT which is smaller than the linewidth (0.022 mT in 4H-SiC and 0.030 mT in 6H-SiC).

IV. SUMMARY

The angular dependence of the $^{13}$C hyperfine lines of the isolated negatively charged vacancy ($V_{Si}^-$) in electron-irradiated 4H-SiC and 6H-SiC has been measured by the X-band cw EPR method. In both 4H-SiC and 6H-SiC, two kinds of $V_{Si}^-$, denoted $V_{Si}^-$ (I) and $V_{Si}^-$ (II), respectively, have been distinguished. The $C_{3v}$ symmetry with the arrangement of the four nearest-neighbor carbon atoms slightly distorted from a regular tetrahedron has been revealed in both $V_{Si}^-$ (I) and $V_{Si}^-$ (II).

From the difference in the degree of distortion from an ideal regular tetrahedron between $V_{Si}^-$ (I) and $V_{Si}^-$ (II) and from the difference in the concentration ratio [$V_{Si}^-$(II)] / [$V_{Si}^-$ (I)] between 4H-SiC and 6H-SiC, $V_{Si}^-$ (I) and $V_{Si}^-$ (II) are assigned to be arising from hexagonal site ($h$) and quasibicubic site(s) ($k$ in 4H-SiC, $k_1$ and $k_2$ in 6H-SiC), respectively. By revealing the $C_{3v}$ symmetry of the isolated vacancy with $S = 3/2$, the important role of electron-electron interaction to attain the high spin configuration is demonstrated.

This work was performed under the management of METI as a part of the METI Project (R&D of Ultra-Low-Loss Power Device Technologies) supported by NEDO.

APPENDIX

The coefficients in Eq. (3) are given as follows: \[ A_1 = \frac{(\mathbf{k} \cdot \mathbf{A} \cdot \mathbf{A} \cdot \mathbf{k}) - K^2}{2}, \] \[ A_2 = \det \mathbf{A}/K, \] \[ A_3 = \text{Tr} \mathbf{A} \cdot \mathbf{A} - (\mathbf{k} \cdot \mathbf{A} \cdot \mathbf{A} \cdot \mathbf{k}), \] \[ K^2 = \mathbf{h} \cdot \mathbf{g} \cdot \mathbf{A} \cdot \mathbf{h}/gK, \] \[ g^2 = \mathbf{h} \cdot \mathbf{g} \cdot \mathbf{h}. \] The symbols $\mathbf{A}$, $\mathbf{g}$, and $\mathbf{h}$ represent the hyperfine matrix, the $g$ matrix, and the unit vector that is parallel to the static field B, respectively. The det $\mathbf{A}$ in Eq. (A2) and the Tr $\mathbf{A}$ in Eq. (A3) indicate the determinant of $\mathbf{A}$ and the trace of $\mathbf{A}$, respectively.

10. Among the terms which induce the zero-field splitting (ZFS), $S^2$ terms are not allowed in the spin Hamiltonian of $S = 3/2$. Since each term must be invariant under the point symmetry operations, there are no $S^2$ terms for cubic symmetry. Thus, ZFS vanishes for $S = 3/2$ in the tetrahedral symmetry, see The Physical Principles of Electron Paramagnetic Resonance (Ref. 11).
