23 **Abstract.** Ongoing climate change is likely to enhance the deterioration of rice quality
24 that has been observed in western Japan, especially Kyushu, since the 1990s. Therefore,
25 it is important to examine the response of rice quality to environmental variation over
26 wide geographical domain. To that end, the aims of this study were (i) to propose a
27 statistical model to predict rice quality based on temperature, total radiation during the
28 ripening period, and their multiple effects; and (ii) to evaluate the model validity and
29 uncertainty in prediction. A Bayesian calibration was adopted to account for uncertainty
30 in the parameter values associated with non-climatic factors. The validation results
31 showed that the model performed well in capturing the temporal trend and interannual
32 variation in observed rice quality in all prefectures, Kyushu. We then performed the
33 prediction experiment for rice quality in the extremely hot summer of the year 2010,
34 which was omitted from the model calibration data. The results showed that the
35 predictive capability of the statistical model is somewhat dependent on the calibration
36 data, but this dependency does not necessarily mean that useful predictions for climates
37 not in the calibration data are impossible.

51 **1. Introduction**

52 Declines in rice quality have been observed in western Japan, especially Kyushu, since the
53 1990s (Morita 2008; Okada *et al.* 2009). Such declines are likely to lower the eating quality of
54 rice (Terao *et al.* 2005; Wakamatsu *et al.* 2007) and reduce farm income and consumer utility in
55 Japan and other countries where the demand for high-quality rice has been increasing.

56 The major reason for the decline in rice quality is the occurrence of chalky grains,
57 especially milky white grains (Morita 2008). Chalky grains sharply increase when the mean
58 daily minimum temperature for the 20 days after heading exceeds 22 °C (Tsukimori 2003). The
59 underlying mechanisms for the occurrence of chalky grains in rice plants are: reduced
60 allocatable carbohydrates in the plant associated with an increased nighttime respiration rate
61 (Vong & Murata 1977; Hirai *et al.* 2003); reduced capacity of stems and leaves for assimilation
62 (Kobata *et al.* 2004; Morita *et al.* 2005); insufficient solar radiation during the ripening period
63 (Matsushima & Manaka 1957); and hits of typhoons during the ripening period (Wakamatsu *et*
64 *al.* 2007).

65 Ongoing climate change may reduce rice quality in the near future. No studies have
66 assessed the possible impact of climate change on rice quality, although some studies have
67 proposed process-based models to predict rice quality based on field experimental results
68 (Nagahata *et al.* 2006; Nakagawa *et al.* 2008). However, these models are designed for
69 prediction at the field scale, and a large gap exists between the spatial scale at which these
70 models operate and the scale at which climate projections are developed. Furthermore, it is
71 difficult to obtain detailed information on cultivars and management practices over large areas,
72 which is essential for a process-based model to simulate the complicated biochemical processes
73 that govern rice quality.

74 Another important issue for impact assessment is uncertainty of the model's applicability to
75 accommodate unprecedented climates, because all impact models are developed and calibrated
76 on the basis of historical data. This corresponds to the uncertainty of future impacts associated
77 with the extrapolation of current knowledge to future unprecedented climates. Therefore, the

78 central objective of impact assessment model validation should be evaluation of the predictive
79 capability of impact models under unprecedented climates.

80 In this study, we propose a statistical model that has a medium level of complexity to
81 predict rice quality at broad spatial scales, that is, the model is less complex than field-scale
82 process-based models but more complex than simple regression models. A Bayesian calibration
83 method (Iizumi *et al.* 2009) was adopted to account for the uncertainty of non-climatic factors
84 (e.g., cultivar and management) in model parameter values. To evaluate the model's capability
85 and applicability for impact assessment, we conducted two types of uncertainty analyses using
86 this model: (i) the sensitivity of the modeled rice quality to temperature increases; and (ii)
87 prediction experiments for the extremely hot summer of 2010, the data from which was not
88 incorporated in the calibration data. The summer of 2010 was the hottest summer in Japan since
89 1898, and the mean temperature anomaly for June, July, and August in that year was 1.64 °C
90 (Japan Meteorological Agency 2011). This resulted in the lowest recorded rice quality in
91 western Japan since collection of comparable statistics was commenced in 1999 (MAFF 2010a).
92 All analyses were carried out for the Kyushu in western Japan (Fig. 1).

93

94 **2. Materials and methods**

95

96 *2.1. Data*

97 According to Japan's Agricultural Products Inspection Act, harvested rice grains are categorized
98 into four grades: first grade, second grade, third grade, and irregular. The major criterion for
99 assigning rice to lower grades is the percentage of chalky grains. Chalky grains are immature
100 and the entire endosperm has a chalky texture, whereas refined whole grains are translucent in
101 appearance (Tashiro & Wardlaw 1991). For rice quality data, we used the proportion of
102 first-grade rice for seven prefectures in Kyushu for the period 1979–2007 from government
103 statistics (MAFF 2010a). The data for 2010 were obtained from a rapid assessment released by
104 the government (MAFF 2010a). Data on heading and harvest dates were obtained from MAFF
105 (2010b).

106 Daily minimum temperature and accumulated solar radiation for the same period were
107 obtained from a grid dataset developed at the National Institute for Agro-Environmental Science
108 (called Mesh-AMeDAS; Seino 1993). The grid interval of the dataset is 30" × 45" in latitude
109 and longitude (about 1 km × 1 km). Land-use data on the same grid interval were obtained from
110 the same dataset. To combine the weather and rice quality data, daily values of the climate
111 variables for grid cells that contained paddy fields ($\geq 20\%$ of a grid cell) were spatially averaged.

112 For model calibration, the data on typhoon track and damage in paddy rice production
113 (MAFF 2010b) were used to exclude rice quality data from years in which severe damages
114 occur in the study areas during the ripening period. The data from 1991, 1993, 2004, and 2006,
115 just four of the 29 years (1979–2007), were removed from the calibration data for Fukuoka. This
116 treatment avoided overfitting the model, considering that typhoon damage to rice quality was
117 not considered in the model.

118

119 *2.2. Rice quality model*

120 We preliminary examined the relationship between rice quality, temperature and total radiation
 121 during the ripening period using the rice quality data from the governmental crop statistics in all
 122 prefectures of Kyushu. The relationships between total radiation for the ripening period and rice
 123 quality at three temperature levels (represented by the mean daily minimum temperature for the
 124 20 days after heading) are shown in Fig. 2. The data show that as temperature increases rice
 125 quality tends to decline. At temperatures <21 °C, most rice quality data have a high percentage
 126 of first-grade rice across the range of radiation. At each higher temperature level (i.e., 21–22.9
 127 and ≥23 °C), the decline in rice quality at lower radiation levels becomes increasingly
 128 pronounced, showing that the sensitivity of rice quality to insufficient radiation increases as
 129 temperature increases.

130 We formulated the statistical relationships between rice quality, temperature, and radiation
 131 from the logistic function:

$$132 \quad Q = Q_{\min}(T) + \frac{Q_{\max} - Q_{\min}(T)}{1 + \exp\{f_a(T)[S - f_b(T)]\}}, \quad (1)$$

133 where Q is the proportion of first-grade rice (%), Q_{\max} and $Q_{\min}(T)$ are the upper and lower limit
 134 of Q (%), respectively, T is the mean daily minimum temperature for n days after heading (°C),
 135 S is the total radiation during the ripening period (MJ m^{-2}), $f_a(T)$ is the sensitivity coefficient of
 136 Q to S , and $f_b(T)$ is the value of S at which rice quality becomes halfway between the upper and
 137 lower limits (i.e., $(Q_{\max} + Q_{\min}(T))/2$).

138 The variables $Q_{\min}(T)$, $f_a(T)$, and $f_b(T)$ were assumed to be linear functions of T to account
 139 for the multiple effects of temperature and radiation on rice quality:

$$140 \quad Q_{\min}(T) = p_1 \cdot T + p_2, \quad (2)$$

$$141 \quad f_a(T) = p_3 \cdot T + p_4, \quad (3)$$

$$142 \quad f_b(T) = p_5 \cdot T + p_6, \quad (4)$$

143 where p_i ($i = 1, \dots, 6$) are parameters.

144 The mean daily minimum temperature for n days after heading, T , and total radiation during

145 the ripening period, S , were represented by:

$$146 \quad T = \frac{1}{n} \sum_{i=1}^n T_{\min i} \quad (5)$$

147 and

$$148 \quad S = \sum_{i=1}^m S_i, \quad (6)$$

149 where $T_{\min i}$ is the daily minimum temperature on the i th day after heading, n is the period after
150 heading in which the temperature has a negative impact on rice quality (days), S_i is the daily
151 total radiation on the i th day after heading ($\text{MJ m}^{-2} \text{ day}^{-1}$), and m is the period from heading to
152 maturity (days). The variable n depends upon non-climatic factors such as the ripening ability of
153 the cultivar, fertilization and irrigation during the ripening period, water temperature, and other
154 factors. These sources of variation were accounted for by Bayesian calibration.

155

156 *2.3. Bayesian calibration*

157 Rice quality non-linearly responds to climate conditions during the ripening period, and a large
158 amount of variation exists that is not explained by climatic factors (Fig. 2). To deal with such
159 variation, we adopted Bayesian calibration for the estimation of the parameter values, p_i ($i=1, \dots,$
160 6) and n for each of the seven prefectures of Kyushu. The general procedure for Bayesian
161 calibration begins by quantifying the known uncertainty of a parameter value in the form of a
162 prior distribution. Observed data corresponding to model output are then used to update the
163 posterior distribution of the parameters by means of Bayes' Theorem:

$$164 \quad p(\theta|D) = \frac{\pi(D|\theta) p(\theta)}{\int \pi(D|\theta) p(\theta) d\theta}, \quad (7)$$

165 where $p(\theta|D)$ is the posterior distribution of the parameter θ for given data D , $\pi(D|\theta)$ is the
166 likelihood function, $p(\theta)$ is the prior distribution of parameter θ , and the denominator of the
167 right-hand side of the eq. 7 is the normalizing constant.

168 The non-informative uniform distributions were here used for the prior distributions of all

169 parameters. The likelihood function was developed on the assumption that errors were
170 distributed normally:

$$171 \quad \pi(\theta) = (2\pi\sigma^2)^{-\frac{N}{2}} \exp\left\{-\frac{(\mathbf{Y} - \hat{\mathbf{Y}})^T (\mathbf{Y} - \hat{\mathbf{Y}})}{2\sigma^2}\right\}, \quad (8)$$

172 where σ^2 is the variance of the error, N is the sample size, and \mathbf{Y} and $\hat{\mathbf{Y}}$ are vectors of the
173 observed and modeled rice quality, respectively.

174 We used the Metropolis–Hastings algorithm to estimate a high-dimensional posterior
175 distribution of parameters via a sampling procedure using the Markov chain Monte Carlo
176 technique (MCMC; Metropolis *et al.* 1953; Hastings 1970). We applied the
177 Metropolis–Hastings algorithm following the procedure described in Iizumi *et al.* (2009)
178

179 3. Results and discussion

180

181 3.1. Posterior distributions of parameters

182 The convergence of the Markov chains to a stationary distribution was examined by checking
183 the Gelman–Rubin statistic (Gelman & Rubin 1992) on the basis of three parallel chains and
184 visually checking the chains. The total number of MCMC iterations was 100,000. Once the
185 chains had reached convergence with reference to the Gelman–Rubin statistic (<1.2), the last
186 10,000 samples per chain (i.e., 30,000 samples in total) were used to obtain the posterior
187 distribution.

188 The posterior distributions of parameters for Fukuoka estimated from the full dataset and
189 from two subsets of the calibration data are shown in Fig. 3. In particular, these subsets
190 excluded the data from year with the hottest (1999, $+1.8\sigma$, where σ represents the standard
191 deviation) or coldest (1980, -2.6σ) summers (represented by the mean daily minimum
192 temperature for n days after heading, T) for the 25-year period to examine the sensitivity of
193 posterior parameter distributions to a particular data from years with an extremely hot or cold
194 temperature condition. For the parameters p_3 , p_4 , and n , little difference was found between the
195 locations of the posterior distributions from the subsets and that from the full set of calibration
196 data, indicating a comparatively low sensitivity of these parameter values to data for a particular
197 year.

198 For the other parameters, the locations of the posterior distribution varied between the
199 subsets and the full dataset, indicating a comparatively high dependency of these parameter
200 values on the particular set of calibration data. The parameters p_1 and p_2 correspond to the slope
201 and intercept term, respectively, to express the linear effect of temperature on the lower limit of
202 rice quality (Eq. 2). For these parameters, the posterior distributions from the subset that
203 excluded data from years with cold summers are very close to that from the full dataset, whereas
204 the posterior distributions from the subset that excluded the data from years with hot summers
205 shifted remarkably away from the distribution for the full set of calibration data. This shows that

206 the presence of the data from years with hot summers in the calibration data is essential to
207 precisely determine the lower limit of rice quality in this model.

208 The parameters p_5 and p_6 are the slope and intercept terms, respectively, of $f_b(T)$. $f_b(T)$
209 denotes the temperature dependence on the threshold value of total radiation for the ripening
210 period, S , that results in the value of rice quality halfway between the upper and lower limits.
211 For these parameters, the posterior distributions from all data were different from those from
212 both subsets. These differences show that the values of these parameters are sensitive to the
213 particular set of calibration data. Both data from years with hot summers and those with cold
214 summer are essential to precisely determine the $f_b(T)$ because both upper and lower values of
215 rice quality are definitely important to determine their half value. Therefore, the lack of either
216 type of data in the calibration data could lead to bias in the parameter values of p_5 and p_6 .

217 Of the seven parameters, the one that can be directly compared with the results of previous
218 studies is the length of the period after heading in which temperature conditions negatively
219 impact rice quality, n . The posterior mean value of n was 30 days, and this is close to other
220 reported values (Nagato & Ebata 1960; Terashima *et al.* 2001; Kondo *et al.* 2006).

221

222 3.2. Model validation

223 We validated the capability of the model to simulate observed rice quality for each prefecture
224 from years that were not included in the calibration data. The leave-one-out cross-validation
225 method (Stone 1974; Geisser 1975) was used. Specifically, we first removed the sample data
226 from one year of the calibration data and estimated the posterior distributions. Then the model
227 was used to simulate the removed data. We repeated these steps for all years.

228 A comparison of the observed and simulated rice quality in Fukuoka for years in which data
229 was removed is shown in Fig. 4. Most observed rice quality was distributed within the range of
230 the ensemble mean ± 1 standard deviation (σ) calculated by perturbing the parameter values
231 within the posterior distributions. The Pearson's correlation coefficient between the simulated
232 and observed rice quality data for the 29-year period was 0.86 ($P < 0.001$). The corresponding

233 root-mean square error was 12.33%. For other prefectures, the calculated goodness-of-fit
234 statistics were somewhat worse than those for Fukuoka, but showed good correspondence
235 between model simulations and corresponding observations (Table1). These results indicate a
236 high capability for the model to capture temporal trends and interannual variation in observed
237 rice quality from climatic factors.

238 Relatively large discrepancies between simulated rice quality and sample data were found in
239 some years, for example, 2005 and 2007 in Fukuoka. These discrepancies can be attributed to
240 factors such as pests, which are not accounted for in the model. Larger than normal outbreaks of
241 brown planthoppers occurred in 2005 and 2007 in Kyushu (Matsumura *et al.* 2007; Watanabe *et*
242 *al.* 2007; Kajisa *et al.* 2008). This suggests that the model will not perform well in years in
243 which non-climatic factors (e.g., pests) are the dominant cause of rice quality decline.

244

245 3.3. Relative impacts of climatic factors on rice quality

246 To quantify the relative impacts of climatic factors on rice quality, we performed sensitivity
247 analysis using artificial increases in temperature for Fukuoka. More specifically, we calculated
248 the change in rice quality per unit change in climatic factor as follows (referred to as the
249 elasticity of rice quality to temperature or radiation):

$$250 \quad \frac{\partial \ln Q}{\partial \ln T} = \frac{\partial Q}{\partial T} \cdot \frac{T}{Q}, \quad (9)$$

$$251 \quad \frac{\partial \ln Q}{\partial \ln S} = \frac{\partial Q}{\partial S} \cdot \frac{S}{Q}. \quad (10)$$

252 We used the posterior mean parameter values for the calculations. A positive sign for elasticity
253 means a positive correlation between rice quality and the climatic factor and vice versa.

254 In this study, we focus only on elasticity of rice quality to temperature and radiation with
255 change in temperature level because little information on the likely effect of climate change on
256 radiation is available. We calculated the elasticities numerically with an artificial temperature
257 data. The artificial temperature data were obtained by adding anomalies to the baseline

258 calculated from the calibration data (= 20.3 °C). The anomalies ranged from -2 to +3 °C in
259 intervals of 0.1 °C. The total radiation during the ripening period was kept constant (= 688.9 MJ
260 m⁻²). This corresponds to the baseline radiation.

261 The calculated elasticity of rice quality to temperature or radiation at various temperature
262 levels is shown in Fig. 5. The sign of elasticity is always negative for temperature and positive
263 for radiation, suggesting that a reduction in rice quality is caused by temperature increase,
264 radiation decrease, or a combination of both. This finding agrees with the results of previous
265 studies (Matsushima & Manaka 1957; Kawatsu *et al.* 2007). Under current temperature
266 conditions, the negative impact of temperature and positive impact of radiation have roughly the
267 same level of elasticity (-5.45 for temperature and 4.78 for radiation), but the negative impact
268 from temperature is slightly stronger with increasing temperature than the positive impact from
269 increasing radiation. For current radiation and management conditions, the tipping point at
270 which the negative impact from increasing temperature becomes 1.5 times larger than the
271 positive impact from radiation is 21.8 °C (corresponds to a temperature increase by +1.5 °C).

272

273 3.4. Prediction of rice quality under unprecedented climates

274 The capability of the model to predict rice quality under unprecedented climates was evaluated,
275 taking the year 2010 with an extremely hot summer as an example. For each of the seven
276 prefectures of Kyushu, we estimated the posterior distributions of parameter from the
277 calibration data without the data from 2010 and then simulated the rice quality from the weather
278 data for that year.

279 The correspondence between the observed and simulated data in 2010 is good in most areas
280 (Fig. 6). Although the model overestimated rice quality in 2010 in most prefectures, a similar
281 tendency was also observed in other years. A comparatively large discrepancy between the
282 observed and simulated data for 2010 appeared in Saga. This is likely due to the rapid
283 introduction of a high-temperature tolerant cultivar 'Sagabiyori' in this area since 2009. Indeed,
284 the proportion of first-grade rice in 2010 was 14.6% for the conventional cultivar 'Hinohikari',

285 but 79.1% for ‘Sagabiyori’ (MAFF 2010a). No persistence of relevant information on a rapid
286 change in the predominant cultivar in the calibration data explains the inaccurate simulation in
287 this area.

288 We further examined the sensitivity of the predictive capability of the model to the
289 calibration data. The Saga data were omitted from this analysis because of the inaccuracy
290 introduced by the change in cultivar. We first obtained the frequency distribution for mean daily
291 minimum temperature for n days after heading from the calibration data and calculated the
292 standard deviation (σ) on the assumption that the frequency distribution could be approximated
293 by a normal distribution. The model was then calibrated for each of four subsets of the
294 calibration data, referred to as CTL, $+1.5\sigma$, $+1.0\sigma$, and $+0.5\sigma$. These subsets except CTL were
295 excluded from years in which the mean daily minimum temperature for n days after heading
296 was greater than the calibration data mean $+1.5\sigma$, mean $+1.0\sigma$, and mean $+0.5\sigma$, respectively,
297 although the CTL subset was not excluded. This meant that in the $+1.5\sigma$ subset, no data from
298 years with very hot summers were included in the calibration data. Therefore, there is no
299 information on the effect of very high temperature conditions on rice quality in the model
300 calibration. As the sample size affects calibration results, for fair treated comparison the sample
301 size was set to be the same among the subsets by removing samples less than $+0.5\sigma$. Finally, we
302 compared the simulation results from the different calibration data with the observed data.

303 The prediction error for 2010 from each subset of calibration data is shown in Fig. 7. In
304 Kagoshima, the model accurately simulated the rice quality in 2010 even when data from years
305 with very hot summers ($> \text{mean} +1.5\sigma$) were removed from the calibration data. The
306 correspondence between observed and simulated data deteriorated if we removed data from
307 years with hot summers ($> \text{mean} +1.0\sigma$) or slightly hot summers ($> \text{mean} +0.5\sigma$). Therefore, the
308 predictive capability of the model is somewhat dependent on the calibration data, but this
309 dependency does not necessarily mean that rice quality cannot be predicted for years with
310 extremely hot summers that are not in the calibration data.

311

312 **4. Conclusion**

313 We propose a statistical model to predict rice quality from climatic factors at large spatial scales.
314 The model accounts for the multiple effects of temperature and radiation during the ripening
315 period. Bayesian calibration was adopted to account for uncertainty due to non-climatic factors
316 in the model prediction. The model accurately reproduced the temporal trend and interannual
317 variation in observed rice quality. However, the model was inaccurate in the occasional years in
318 which non-climatic factors dominated the quality results.

319 The sensitivity analysis showed that an increase in temperature has a negative effect on rice
320 quality, whereas an increase in radiation has a positive effect. Under present climate conditions,
321 these two climatic factors affect rice quality to a similar extent. However, the negative effect
322 from temperature becomes larger compared to the positive effect from radiation as average
323 temperature during the ripening period increases. This suggests that climate change will cause a
324 decline in rice quality, all other things being equal.

325 The predictive capability of the model is somewhat dependent on the calibration data.
326 However, the model is still reliable even when data from years with very hot summers were not
327 included in the calibration data, indicating that at least a modest level of extrapolation for future
328 climate is possible. Some projection results for regional climate change impacts based on
329 climate model projection were reported as a separate paper.

330 Future research should examine the impacts of atmospheric CO₂ concentration on rice
331 quality. Such information is currently scarce, and datasets of the spatial distribution of
332 atmospheric CO₂ concentration do not exist in the same way as they do for temperature and
333 radiation. Additional systematic exploration of the sensitivity of the predictive capability of the
334 model to the calibration data would also assist in determining the applicability of the model to
335 wider temporal domain.

336

433 **Table captions**

434 Table 1. The Pearson's correlation coefficient (R) with statistical significance (***, $P < 0.001$;
435 **, $P < 0.01$) and the root-mean-square error (RMSE) between the observed and simulated
436 ensemble mean rice quality for seven prefectures in Kyushu.

437

438 **Figure captions**

439 Fig. 1. Location of Japan (left) and the Kyushu (right), with the seven prefectures labeled. Blue
440 shaded areas indicate grid cells that contained paddy fields over 20% of a grid cell.

441

442 Fig. 2. Relationships for observed rice quality (represented by the proportion of first-grade rice)
443 versus total radiation during the ripening period at three temperature levels (represented by the
444 mean daily minimum temperature during the 20 days after heading, T_{20}). Curves indicate the
445 logistic regressions fitted to the data at each temperature level annotated with their correlation
446 coefficients (R) and statistical significance (***, $P < 0.001$; **, $P < 0.01$; and *, $P < 0.05$).

447

448 Fig. 3. Posterior distributions of seven model parameters for a model of rice quality as a
449 function of temperature and radiation developed for Fukuoka from 25 years of calibration data
450 (shaded area) or from subsets of the same data, excluding data from years with particularly hot
451 (dashed line) or cold (solid line) summers.

452

453 Fig. 4. Time series of observed (Obs.) and simulated ensemble mean (Est.) rice quality in
454 Fukuoka. The shaded region indicates the range of the ensemble mean ± 1 standard deviation
455 produced by perturbing parameter values. Open diamonds indicate the observed data in typhoon
456 years that were removed from the calibration data. The values for Pearson's correlation
457 coefficient (R ; $P < 0.001$) and the root-mean-square error (RMSE) between the observed and
458 simulated ensemble mean data are shown.

459

460 Fig. 5. Elasticity of rice quality to temperature or radiation at various temperature levels
461 (represented by the mean daily minimum temperature for 30 days after heading)

462

463 Fig. 6. Comparison of 2010, which had an extremely hot summer, with other years with respect
464 to observed (Obs.) versus simulated ensemble mean (Est.) rice quality for the seven Kyushu

465 prefectures.

466

467 Fig. 7. Absolute prediction errors between the observed and simulated ensemble mean rice
468 quality for three areas in Kyushu in 2010, a year with an extremely hot summer. For each area,
469 the horizontal axis indicates subsets of the calibration data in which data from very hot ($+1.5\sigma$),
470 hot ($+1.0\sigma$), or slightly hot ($+0.5\sigma$) summers were removed. For reference, the result from
471 calibration data including data in very hot summer years is also shown (CTL). Error bars
472 indicate the range of the ensemble mean ± 1 standard deviation produced by perturbing the
473 parameter values.

474

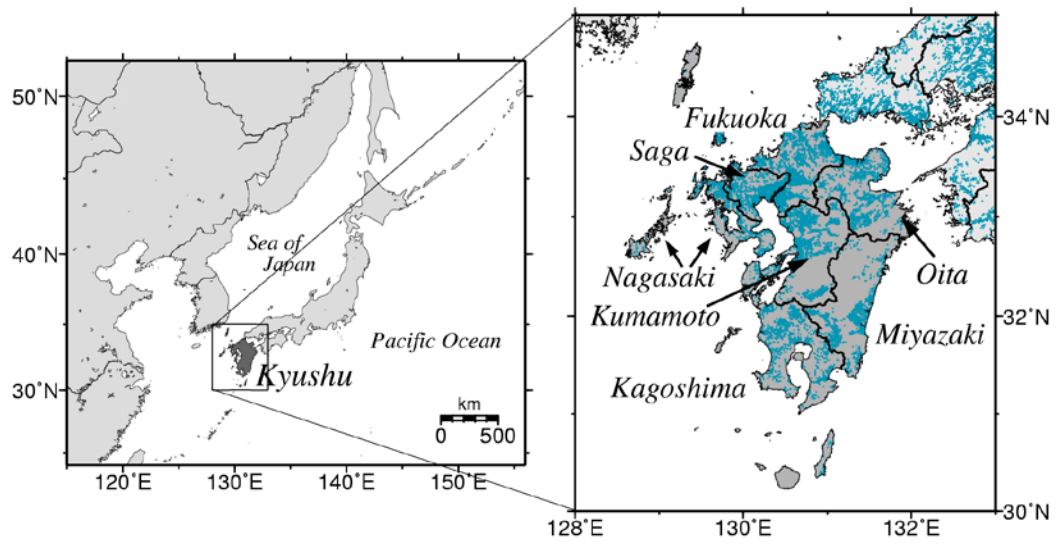

475 Table 1. The Pearson's correlation coefficient (R) with statistical significance (***, $P < 0.001$;
 476 **, $P < 0.01$) and the root-mean-square error (RMSE) between the observed and simulated
 477 ensemble mean rice quality for seven prefectures in Kyushu..

Prefecture	R [-]		RMSE [%]
Fukuoka	0.86	***	12.33
Saga	0.62	***	19.74
Nagasaki	0.68	***	18.22
Kumamoto	0.54	**	19.46
Oita	0.61	***	16.51
Miyazaki	0.68	***	13.94
Kagoshima	0.67	***	14.65
