(Received 7 June 2012; published 2 November 2012)

We perform a nonperturbative calculation of the \( \pi^0 \to \gamma \gamma \) transition form factor and the associated decay width using lattice QCD. The amplitude for a two-photon final state, which is not an eigenstate of QCD, is extracted through a Euclidean time integral of the relevant three-point function. We utilize the all-to-all quark propagator technique to carry out this integration as well as to include the disconnected quark diagram contributions. The overlap fermion formulation is employed on the lattice to ensure exact chiral symmetry on the lattice. After examining various sources of systematic effects, except for a possible discretization effect, we obtain \( \Gamma_{\pi^0 \to \gamma \gamma} = 7.83(31)(49) \) eV for the pion decay width, where the first error is statistical and the second is our estimate of the systematic error.

The neutral pion decay process provides a unique opportunity to test a fundamental symmetry property of the gauge theory. A quantum effect due to a fermion loop violates the axial-current conservation, and gives the dominant contribution to the \( \pi^0 \to \gamma \gamma \) decay rate. The prediction from this Adler-Bell-Jackiw (ABJ) anomaly [1,2] (or the chiral anomaly) is rather precise because higher-loop diagrams do not contribute in the limit of vanishing quark mass and external momenta [3] even under the presence of strong interaction. On the other hand, a recent experimental measurement of the neutral pion decay width has reached the accuracy of 2.8% [4] and is aiming to achieve 1.4% in the near future. At this level of accuracy, the correction due to finite quark mass becomes relevant. Phenomenologically, an enhancement of the decay width of about 3–5% has been expected according to the sum rule and chiral perturbation theory (\( \chi \)PT) approaches [5–8], in which the main effect comes from a mixing of \( \pi^0 \) with \( \eta \) and \( \eta' \) mesons. For a recent review, we refer the reader to Ref. [9].

In this Letter we present a model-independent calculation of the \( \pi^0 \to \gamma \gamma \) amplitude using the lattice quantum chromodynamics including dynamical up, down, and strange quarks. We use the overlap fermion formulation [10], which preserves chiral symmetry at finite lattice spacings. In this formulation, the chiral anomaly appears through the Jacobian of chiral transformation; the Atiyah-Singer index theorem is reproduced as far as the background gauge field is smooth enough [11]. On the other hand, whether the chiral anomaly is correctly reproduced at practically used lattice spacings (~ 0.1 fm) is a nonperturbative problem, one that we address in this work.

Compared to previous attempts [12,13], a new technique is applied to treat the two-external-photon state, by utilizing the all-to-all quark propagator [14,15]. In the limit of degenerate up and down quark masses, we obtain the decay rate with a statistical error of 4% and a total error of 7% after examining possible systematic effects.

The \( \pi^0 \to \gamma \gamma \) decay rate at the leading order of QED can be expressed as

\[
\Gamma_{\pi^0 \to \gamma \gamma} = \frac{\pi\alpha_e^2 m_\pi^3}{4} \mathcal{F}_{\pi^0 \to \gamma \gamma}^2(m_\pi^2, 0, 0),
\]

where \( \alpha_e \) is the fine structure constant, \( m_\pi \) is the neutral pion mass, and \( \mathcal{F}_{\pi^0 \to \gamma \gamma}(m_\pi^2, p_1^2, p_2^2) \) is the form factor of the pion to two (virtual) photon transition with \( p_{1,2} \) the photon momenta. In the chiral limit, the ABJ anomaly predicts

\[
\mathcal{F}_{\pi^0 \to \gamma \gamma}^{\text{ABJ}} \equiv \mathcal{F}_{\pi^0 \to \gamma \gamma}(0, 0, 0) = \frac{1}{4\pi^2 F_0},
\]

where \( F_0 \) is the pion decay constant \( F_\pi \) in the chiral limit. We define a normalized form factor as \( F(m_\pi^2, p_1^2, p_2^2) = (4\pi^2 F_\pi) \mathcal{F}_{\pi^0 \to \gamma \gamma}(m_\pi^2, p_1^2, p_2^2) \). In the Minkowski space-time, \( \mathcal{F}_{\pi^0 \to \gamma \gamma}(m_\pi^2, p_1^2, p_2^2) \) is defined through the matrix element
\[ M_{\mu \nu}(p_1, p_2) = i \int d^4x e^{i p_1 \cdot x} \langle 0 | T[j_\mu(x) j_\nu(0)] | \pi^0(q) \rangle = e_{\mu \nu \alpha \beta} p_1^\alpha p_2^\beta \mathcal{F}_{\pi^0 \gamma \gamma} (m_\pi^2, p_1^2, p_2^2), \]  
\tag{3}

where \( q \) is the \( \pi^0 \) momentum satisfying the on-shell condition \( q^2 = m_\pi^2 \). The current \( j_\mu = \sum_f Q_f \bar{q}_f \gamma_\mu q_f \) is the hadronic component of the electromagnetic vector current and the sum runs over all relevant quark flavors: \( f = u, d, s, \bar{c}, \bar{b}, q \) denotes the electromagnetic charge of them: \( Q_u = +2/3 \) and \( Q_d = -1/3 \). The factor \( e_{\mu \nu \alpha \beta} p_1^\alpha p_2^\beta \) is induced by the negative parity of \( \pi^0 \).

By an analytic continuation of (3) from the Minkowski space-time [16,17], one may write

\[
M_{\mu \nu}(p_1, p_2) = \lim_{t_1, t_2 \to -\infty} \frac{1}{2E_{\pi q}} e^{-E_{\pi q}(t_1 - t_2)} \int d^4x e^{-i p_1 \cdot x} C_{\mu \nu}(t_1, t_2, t_\pi),
\]

\[
C_{\mu \nu}(t_1, t_2, t_\pi) = \int d^3 \vec{z} e^{-i \vec{p}_1 \cdot \vec{z}} \int d^3 \vec{z} e^{i \vec{p}_2 \cdot \vec{z}} \langle \Omega | T[j_\mu(\vec{z}, t_1) j_\nu(\vec{0}, t_2) \pi^0(\vec{z}, t_\pi)] | \Omega \rangle,
\tag{4}
\]

where \( t_1, t_2, \) and \( t_\pi \) are Euclidean time slices. \( \int d^3 \vec{z} e^{i \vec{p}_1 \cdot \vec{z}} \pi^0(\vec{z}, t_\pi) \) is an interpolating operator for the neutral pion with the spatial momentum \( \vec{q} \). Its amplitude and energy in the ground state are denoted by \( \phi_{\pi, \vec{q}} \) and \( E_{\pi, \vec{q}} \), respectively. The four-momentum of the first photon \( p_1 = (\omega, \vec{p}_1) \) is chosen as input, while the momentum of the second photon is given as \( p_2 = (E_{\pi, \vec{q}} - \omega, \vec{q} - \vec{p}_1) \) by momentum conservation. Note that the analytical continuation is valid only for \( p_1^2, p_2^2 < M_V^2 \), which sets the limit on the value of \( \omega \). (\( M_V \) stands for the invariant mass of the lowest energy state in the vector channel.) Since the two photons cannot be on-shell simultaneously, we calculate the form factor at the off-shell photon momenta and then extrapolate to the on-shell limit.

To calculate the matrix element \( \langle \Omega | j_\mu j_\nu \pi^0 \Omega \rangle \) in Eq. (4), we use 2 + 1-flavor overlap fermion configurations generated by the JLQCD and TWQCD Collaborations [18,19] at a single lattice spacing \( a = 0.11 \) fm and two spatial lattice sizes \( L/a = 16 \) and 24. The time extent is \( T/a = 48 \). Although the main gauge ensembles have a fixed (global) topological charge \( Q = 0 \), the deviation from the \( \theta \) vacuum is understood as a finite volume effect of \( O(1/L^3) \) [20]. We check the significance of this effect by comparing the results with two different values \( Q = 0, 1 \). We utilize the all-to-all propagator to calculate the correlation function \( C_{\mu \nu}(t_1, t_2, t_\pi) \) at any time slices of \( t_1, t_2, \) and \( t_\pi \). The electromagnetic current \( j_\mu = \sum_f Q_f \bar{q}_f \gamma_\mu q_f \) is implemented on the lattice as a local operator with a renormalization factor calculated nonperturbatively in [21] to match the lattice results with the continuum theory. The up and down quarks are degenerate in mass. We use the bare values \( m_{u,d} = 0.015, 0.025, 0.035, \) and 0.050, corresponding to the pion mass \( m_\pi \) ranging from 290 to 540 MeV. Our final results are obtained by an extrapolation of the data to the physical pion mass \( m_\pi, \text{phys} \). The strange quark mass is fixed at \( m_s = 0.080 \), which is very close to the estimated physical value.

From the large \( t_1, t_2 \to t_\pi \) behavior of \( C_{\mu \nu}(t_1, t_2, t_\pi) \), it is possible to extract the \( \pi^0 \) ground state. We define the amplitude \( A_\pi \) as

\[
A_\pi(\tau) \equiv \lim_{t_\pi \to -\infty} C_{\mu \nu}(t_1, t_2, t_\pi) / e^{-E_{\pi q}(t_\pi - t_\tau)}, \tag{5}
\]

with \( \tau = t_1 - t_2 \) and \( t = \min(t_1, t_2) \), and obtain \( M_{\mu \nu}(p_1, p_2) \) by performing an integration,

\[
\frac{2E_{\pi q}}{\phi_{\pi}} \left( \int_0^\infty d\tau e^{i\omega\tau} A_\pi(\tau) + \int_{-\infty}^0 d\tau e^{i\omega\tau} A_\pi(\tau) \right). \tag{6}
\]

We use two momentum setups \( \vec{p}_1 = \frac{2\pi}{L}(0, 0, 1) \) (setup 1) and \( \vec{p}_1 = \frac{2\pi}{L}(0, 0, 1) \) (setup 2). The resulting amplitudes \( A_\pi(\tau) \) for these setups are shown in Fig. 1. In order to qualitatively understand the \( \tau \) dependence of the \( A_\pi(\tau) \), we consider the vector-meson-dominance (VMD) model \( \mathcal{F}_{\pi^0 \gamma \gamma} = c_{V} G_{V}(p^2)^2 / (M_V^2 - p^2) \) and \( G_{V}(p^2) = \frac{m_{\pi}^2}{M_V^2} / (M_V^2 - p^2) \) the vector-meson propagator and \( c_{V} \) a constant. The amplitude \( A_V^{\text{VMD}}(\tau) \), reconstructed from this model, is plotted by red solid curves in Fig. 1. (The detailed expression for \( A_V^{\text{VMD}}(\tau) \) will be given in a later publication [22]). We find that the VMD model describes the lattice data at \( |\tau|/a = 7 \), and we can safely evaluate the contribution beyond \( |\tau|/a = 13 \), where the lattice data are truncated due to the finite time extent \( T \). At small \( |\tau| \), the VMD model fails to match the lattice data. This is because no information about the vector-meson excited states is contained in \( \mathcal{F}_{\pi^0 \gamma \gamma} \). Given the dominant role played by

![FIG. 1](color online) The amplitude \( A_\pi(\tau) \) as a function of \( \tau \) for momentum setup 1 (left) and setup 2 (right). The black dashed (red solid) curves indicate the lattice (VMD) amplitudes.
of this work. Such an effect could become significant for precision
which vanishes in the continuum limit. The leading FS
effect, we therefore use the data with

\[ F(\pi^2, 0, 0) = \frac{1}{F_{\pi^2}'(0, 0)} \]

as a function of \( m_\pi^2 \). In the chiral and large volume limit
for each panel, data with \((L/a, Q) = \) (16, 0), (24, 0), and
(16, 1) are plotted by the blue circles, red squares, and green
diamonds, respectively. The yellow stars indicate the Particle
Data Group (PDG) [27] or PrimEx Collaboration [4] experimental
values, for reference. The solid (dashed) curves show the
result of the fit to the linear (quadratic) function. The data set
used in the fit is explained in the text.

By varying \( \omega \), we obtain \( M_{\mu, \alpha}(p_1, p_2) \) in a certain range
of \( p_1^2 \) and \( p_2^2 \). As shown in the left panel of Fig. 2, a pair
\((p_1^2, p_2^2) = \{\omega^2 - p_1^2, (E_{\pi, a} - \omega) - (q - p_1)^2\} \) forms a
continuous contour on the \((p_1^2, p_2^2) \) plane for \( p_1^2, p_2^2 <
M_T^2/2 \). Evaluating \( F_{\pi^2, l}(m_\pi^2, p_1^2, p_2^2) \) along this contour,
we obtain the data plotted in the right panel of Fig. 2. We perform
the combined fit of these data to Eq. (7) with four
free parameters: \( c_V, c_0, c_0_0, \) and \( c_0_1 = c_1_0 \), truncating the
higher-order terms which turned out to be negligibly
small. The fitting curves are shown in the right panel of
Fig. 2. As expected, the single formula (7) describes the
data with different momentum setups. Combining the
resulting fit parameters, we obtain the normalized form
factors \( F(m_\pi^2, 0, 0) \), which are plotted in the uppermost
panel of Fig. 3.

In the following, we analyze the details of systematic
effects. When calculating the integral in Eq. (6), we use the
summation instead of the integration. This causes a
discretization effect, which vanishes in the continuum limit.
Putting \( A_{\pi}^{\text{MD}}(\tau) \) into Eq. (6), we find that the fractional
difference between \( M_{\mu, \alpha}(p_1, p_2) \) from the summation and
the integration is less than \( 5 \times 10^{-4} \). With the lattice data
that include the excited state contributions, we could
expect a larger error, \( \sim 1 \times 10^{-3} \), which is estimated
from a difference between VMD and lattice data in
Fig. 1. We can therefore safely neglect this source of error
as it is well below 1%.

We use two lattice volumes and two topological-charge
sectors to check finite-size (FS) effects. Following
Ref. [20], we analyze the fixed-topology (FT) effect and
find it suppressed due to the kinematical structure of
\[ \varepsilon_{\mu, \alpha, \beta} p_1^\mu p_2^\beta. \] By comparing the lattice results at different
topological-charge sectors, we do not observe statistically
significant FT effects. The leading FS effect in
\( C_{\mu, \alpha}(t_1, t_2, \tau) \) is the conventional one and known to behave
as \( e^{-m_\pi L} \) [23]. To reduce the contamination due to this
effect, we therefore use the data with \( m_\pi L \geq 4 \) to perform
the chiral extrapolation. (Namely, we exclude the \( L/a =
16 \) data points at the lowest two pion masses.)

\[ \chi \text{PT shows that up to next-to-leading order (NLO) the}
\]
\( m_\pi \) dependence of \( F(m_\pi^2, 0, 0) \) involves no chiral
logarithm [24,25]. We therefore simply fit \( F(m_\pi^2, 0, 0) \)
by a linear function in \( m_\pi^2 \), and obtain \( F(0, 0, 0) = 1.016(20) \)
and \( F(m_\pi^2, 0, 0) = 1.011(19) \). To check the higher-order
correction, we also perform a quadratic fit under the
constraint from the ABJ anomaly: \( F(0, 0, 0) = 1 \). We do not
find any statistically significant difference due to the
higher-order term. The linear (quadratic) fit is shown by
the solid (dashed) line in the uppermost panel of Fig. 3.
Next we consider the data with $m_\pi L < 4$, which tend to suffer from the FS effect. As shown in Fig. 3, at $m_\pi \approx 290$ MeV we find that $F(m_\pi^2, 0, 0)$ calculated at the $L/a = 16$ lattice is 27% less than the one at $L/a = 24$. Although large, such FS effect is understandable. By inserting the ground state into $\langle j_\mu j_\nu \pi^0 \rangle$, we can approximate this three-hadron matrix element,

$$\langle j_\mu j_\nu \pi^0 \rangle \to \langle \Omega | j_\mu | V, e \rangle (V, e | j_\nu | \pi^0) (\pi^0 | \pi^0 | \Omega) .$$

The first matrix element is related to the electromagnetic coupling $g_V$ as $\langle \Omega | j_\mu | V, e \rangle = M_V^2 g_V e_\mu$, the second is proportional to the $V\pi\gamma$ coupling $g_{V\pi\gamma}$, and the third is related to $F_\pi$ by the partially-conserved-axial-vector-current constraint (PCAC) relation. In our calculation, we do not observe a significant FS effect in $M_V$ but find 8%, 7%, and 9% shifts in $g_{V\pi\gamma}$, and $F_\pi$, respectively, from $L/a = 16$ to 24, as shown in Fig. 3. These FS effects may accumulate in the three-point function. We estimate the FS corrections $R_O = O(\infty)/O(L)$ with $O = g_V$, $g_{V\pi\gamma}$, and $F_\pi$, $R_{g_V}$ and $R_{g_{V\pi\gamma}}$ are evaluated by adding a correction term, $e^{-m_\pi L}$, into the linear fit form in the chiral extrapolation of each quantity. With such corrections taken into account, we confirm that their chiral limit is consistent with experimental data. $R_{F_\pi}$ is calculated to NNLO by using $\chi$PT [26]. Assuming that $R_{F(m_\pi^2, 0, 0)} = R_{F_\pi} R_{g_{V\pi\gamma}} R_{g_V}$, we may correct $F(m_\pi^2, 0, 0)$ by a factor of $R_{F(m_\pi^2, 0, 0)}$. As shown in the lowest panel of Fig. 3, with FS correction $F(m_\pi^2, 0, 0)$ at $L/a = 16$ agrees with those at $L/a = 24$. Using the corrected data to perform a linear extrapolation, we obtain $F(0, 0, 0) = 1.045(35)$ and $F(m_\pi^2, 0, 0) = 1.041(32)$. The difference between the results from the two methods is considered as a systematic error.

So far, our results are obtained neglecting the effect of disconnected diagrams that may appear because the electromagnetic current $j_\mu$ contains a flavor-singlet contribution. Calculation of the disconnected diagram is computationally demanding and statistically noisy. We solve these problems by the use of the all-to-all propagator. The full data, including both the connected and disconnected contributions, are plotted in the upper (lower) panel of Fig. 4 for the case without (with) the FS correction. We find that, although not significant, there is a shift from the connected data to the full ones. Since the accuracy of our calculation reaches a few-percent level, the disconnected effect is relevant. Using the full data, we repeat the analysis. The linear fit of $F(m_\pi^2, 0, 0)$ with $m_\pi L \geq 4$ yields $F(0, 0, 0) = 1.009(22)$ and $F(m_\pi^2, 0, 0) = 1.005(20)$. The fit with FS corrected $F(m_\pi^2, 0, 0)$ produces $F(0, 0, 0) = 1.007(36)$ and $F(m_\pi^2, 0, 0) = 1.006(33)$. Including the disconnected contributions, the normalized form factor in the chiral limit and at the physical pion mass shifts by 1–4%. This is comparable to the statistical error.

Using the full data, we quote our results for $F(m_\pi^2, 0, 0)$ and $\Gamma_{\pi^0\gamma\gamma}$ in the isospin symmetric limit as

$$F(0, 0, 0) = 1.009(22),$$
$$F(m_\pi^2, 0, 0) = 1.005(20),$$
$$\Gamma_{\pi^0\gamma\gamma} = 7.83(31)(49) \text{ eV},$$

where the systematic errors originate from the difference of the results by using two methods of treating the FS effect. (The difference appearing in the full data is small. To be conservative, we use the connected data to estimate such systematic error.) Our results reproduce the predication of the ABJ anomaly $F(0, 0, 0) = 1$ and agree with the PrimEx Collaboration measurement $\Gamma_{\pi^0\gamma\gamma} = 7.82(22)$ eV [4]. For future improvements, isospin breaking effects due to the light quark mass difference need to be included.

Numerical simulations were performed on the Hitachi SR16000 at Yukawa Institute of Theoretical Physics and at High Energy Accelerator Research Organization under support of its Large Scale Simulation Program (No. 10-11). This work is supported in part by Grant-in-Aid of the Japanese Ministry of Education (Nos. 21674002 and 21684013), the Grant-in-Aid for Scientific Research on Innovative Areas (Nos. 20105001, 20105002, 20105003, 20105005, and 23105710), and the HPCI Strategic Program of the Japanese Ministry of Education.
