Femtosecond structural transformation of phase-change materials far from equilibrium monitored by coherent phonons

Muneaki Hase¹, Paul Fons², Kirill Mitrofanov², Alexander V. Kolobov² & Junji Tominaga²

Multicomponent chalcogenides, such as quasi-binary GeTe-Sb₂Te₃ alloys, are widely used in optical data storage media in the form of rewritable optical discs. Ge₂Sb₂Te₅ (GST) in particular has proven to be one of the best-performing materials, whose reliability allows more than 10⁶ write-erase cycles. Despite these industrial applications, the fundamental kinetics of rapid phase change in GST remain controversial, and active debate continues over the ultimate speed limit. Here we explore ultrafast structural transformation in a photoexcited GST superlattice, where GeTe and Sb₂Te₃ are spatially separated, using coherent phonon spectroscopy with pump-pump-probe sequences. By analysing the coherent phonon spectra in different time regions, complex structural dynamics upon excitation are observed in the GST superlattice (but not in GST alloys), which can be described as the mixing of Ge sites from two different coordination environments. Our results suggest the possible applicability of GST superlattices for ultrafast switching devices.

The rapid phase change in $\text{Ge}_2\text{Sb}_2\text{Te}_5$ (GST) materials involved in the writing (from crystalline to amorphous) and erasing (from amorphous to crystalline) of data in optical recording media is induced by irradiation with focused nanosecond laser pulses, leading to melt-quenching (amorphization) and annealing (crystallization), respectively^{1–3}. The same concept has been applied to electrical memory with electrical pulses replacing optical pulses and resistance differences replacing reflectivity changes⁴. Thus, the conventional understanding of the dynamics of rapid phase change in optical recording media using GST materials is based on a thermal process, limiting the speed of the write–erase cycle to the nanosecond range^{1,2}. In electronic memories, the terms SET and RESET phases are used to describe the two structural phases^{4,5}. By analogy, we use the same terminology here, although it is not commonly used with respect to optical memory. SET refers to the local structure in the crystalline phase of GST, typically characterized by resonantly bonded atoms with three shorter and three longer bonds, also referred to as octahedrally coordinated^{6,7} when differences in the bond lengths are neglected, and RESET refers to the covalently bonded amorphous phase, described as having tetrahedral⁸, defective octahedral⁹ or pyramidal¹⁰ Ge sites. The microscopic mechanism of rapid phase change in GST has been examined using optical absorption¹¹, Raman scattering and X-ray absorption fine-structure (XAFS) measurements⁸, as well as density functional theory-based *ab initio* molecular dynamics simulations^{3,12,13}.

Interfacial phase-change memory (iPCM) consists of a superlattice (SL) structure formed from alternating layers of GeTe and Sb_2Te_3 (refs 7,14). iPCM was designed to utilize a solid–solid phase transformation between the covalently bonded (RESET) and resonantly bonded (SET) phases, induced predominantly by the displacement of Ge atoms at the interface, to achieve both faster and lower power threshold switching than in conventional GST alloys⁷. iPCM structures with certain thicknesses and atomic order in the individual blocks were also argued to be topological insulators, and recently, it was reported that iPCM could be switched between the Dirac-semimetal and gapped phases¹⁵, an effect that has the potential to lead to novel spin memory devices and also as a platform to study the topological properties of SLs.

Non-thermal phase transitions (electronic excitation-induced phase transitions^{16,17}) induced via strong photoexcitation by femtosecond laser pulses with sub-picosecond time resolution have been reported for a wide variety of materials including semiconductors¹⁶, manganites¹⁸ and insulators¹⁹. Recently, the possibility of non-thermal phase change has been theoretically^{13,17} and experimentally^{20,21} proposed for GST alloys. In an important step, Fons *et al.*²¹ reported based on time-resolved XAFS measurements that non-thermal optically induced contributions to the amorphization in GST alloy may be present on sub-nanosecond timescales. As a further step, using weak femtosecond laser pulses with pump fluences below $100 \mu\text{J cm}^{-2}$, Makino *et al.*²² demonstrated that for a prototypical iPCM structure, $[\text{Ge}_2\text{Te}_2/\text{Sb}_2\text{Te}_3]_{20}$, a phase change from the RESET into the SET phase could be induced by selectively exciting a phonon mode that involves Ge atoms using a double-pulse excitation. Despite recent activity investigating non-thermal phase transitions in GST alloys and iPCM, the mechanism of the non-thermal phase transformation remains largely unknown, especially at sub-picosecond timescales under strong photoexcitation.

In the following, we report on systematic studies of the structural dynamics in a prototypical iPCM structure, $[\text{Ge}_2\text{Te}_2/\text{Sb}_2\text{Te}_3]_{20}$, using coherent phonon spectroscopy (CPS) under strong photoexcitation employing both single- and double-

pump-pulse excitation. In the SET phase of iPCM, we observe marked differences between the pre-translational dynamics induced by single- and double-pulse excitation. Under single-pulse excitation, only phonon softening is observed for an optical phonon mode involving Ge–Te bonds. In contrast, under double-pulse excitation the optical phonon frequency exhibits an unexpected blue shift (hardening), accompanied by the appearance of an additional peak in the coherent phonon spectra when the interval between the two pump-pulses is shorter than a few picoseconds and exceeds a critical total pump fluence. Furthermore, we find that the structural change dynamics in the photoexcited SET phase of iPCM are reversible, while those in the RESET phase of iPCM are irreversible. A metastable pre-phase transformation state with characteristic coherent phonon spectra in the SET phase of iPCM at ultrafast timescales suggests the presence of two different coordination environments around Ge atoms. Exploration of the non-thermal pre-phase transformations in GST materials will enable a deeper understanding of the local lattice structure far from equilibrium, and will potentially make it possible to increase the speed limit of switching in the phase-change process beyond the current limit of nanoseconds down to sub-picosecond timescales.

Results

Transient reflectivity studies of the SET phase of iPCM.

Figure 1a depicts a schematic view of the pump–pump–probe experiment^{22,23}. To explore the coherent phonon spectra under non-equilibrium conditions prepared by photoexcitation (Fig. 1b), a stronger initial prepump-pulse ($P_1 = 10.6 \text{ mJ cm}^{-2}$) promotes the sample into the excited state, followed by the generation of a coherent phonon in the excited state by another weaker pump ($P_2 = 6.9 \text{ mJ cm}^{-2}$), which is monitored by a probe pulse ($P_3 = 0.2 \text{ mJ cm}^{-2}$). The weaker pump (P_2) acts as a control pulse to coherently launch the vibrational amplitude beyond the threshold of transient local phase change around the Ge atoms²²; use of a P_2 pulse fluence less than 2.0 mJ cm^{-2} does not induce phonon hardening (Supplementary Fig. 1). The choice of fluences $P_1 = 10.6 \text{ mJ cm}^{-2}$ and $P_2 = 6.9 \text{ mJ cm}^{-2}$ was made because of the low-limit threshold for the observation of phonon hardening in iPCM as discussed below and also to allow for matching the phonon amplitude resulting from the initial excitation at the time delay $\tau = 0 \text{ fs}$ with the phonon amplitude induced by the second excitation pulse at the separation time (Δt) of $\Delta t = 290\text{--}870 \text{ fs}$ (see Methods). The time delay (τ) between the second pump and the probe pulse was scanned over the full range of the signal, for a variety of separation times (Δt) between P_1 and P_2 pulses.

Figure 2a shows the transient reflectivity ($\Delta R/R$) observed in the SET phase of an iPCM film without prepump-pulse (P_1) excitation (see the bottom trace) and five major traces observed for P_1 excitations at different Δt . One can notice that the coherent phonon oscillations in the excited state, highlighted by the rectangular light-blue region, change markedly as the value of Δt is varied; in particular, at $\Delta t = 290\text{--}870 \text{ fs}$, the coherent phonon after the arrival of the P_2 pulse exhibits a strongly damped oscillation. To compare the $\Delta R/R$ signal observed in iPCM under irradiation with double pump-pulses with that occurring for irradiation with a single pump-pulse, Fig. 2b presents the transient reflectivity detected in the SET phase of an iPCM film by irradiation with a single P_2 pulse at different pump fluences. The coherent phonon oscillations exhibited an increase in amplitude with moderate damping of the phonon oscillation when the P_2 pulse fluence was increased up to 18.6 mJ cm^{-2} . To explore the phonon dynamics in the frequency domain, coherent oscillations occurring only after the arrival of the P_2 pulse, that is, the time region highlighted by the rectangular light-blue region in

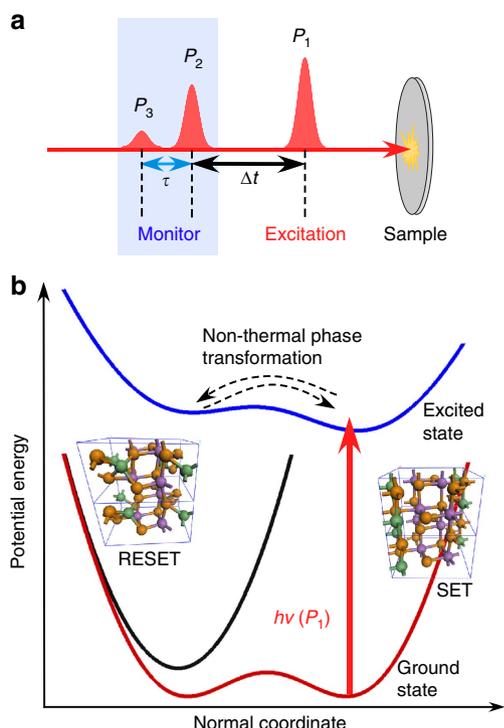

Figure 1 | Coherent phonon spectroscopy in the photoexcited state.

(a) Schematic of the pump-pump-probe experiment, showing photoexcitation of the system from the ground state into the excited state with a prepump-pulse ($P_1 = 10.6 \text{ mJ cm}^{-2}$), followed by generation of a coherent phonon in the excited state with another weak pump ($P_2 = 6.9 \text{ mJ cm}^{-2}$), which is monitored by a probe pulse ($P_3 = 0.2 \text{ mJ cm}^{-2}$). (b) Schematic of the potential energy surface, together with the local structural change of the iPCM. The ground state of the SET phase (red curve) is characterized by an anharmonic potential, whose activation energy barrier is larger than the difference in the free energy between the SET and RESET (black curve) phases¹⁴. The photoexcitation ($h\nu = 1.55 \text{ eV}$) promotes the ground state into the excited state (blue curve), where the non-thermal phase transformation can be induced and monitored by pump-pump-probe coherent phonon spectroscopy. The local structures in the two ground states were calculated by first-principle simulations²². The green balls represent Ge atoms, the orange balls are Te atoms and purple balls are Sb atoms.

Fig. 2a (the entire region for the case of a single P_2 pulse in Fig. 2b), were Fourier transformed (FT)²⁴.

Without the P_1 excitation, the frequency of the coherent phonon was $\Omega_{\text{SET}} = 3.48 \text{ THz}$ (see Fig. 3a), and was slightly red-shifted from the literature value^{22,25}, but remained consistent with the optical mode due to the local Ge-Te bonds of the resonantly bonded structure^{22,25}. Similar phonon softening induced by single pump excitation has also been observed in conventional GST alloy films²⁶. The choice of the value of Δt is based on the period of the coherent phonon observed without prepump-pulse excitation; 3.48 THz corresponds to $\approx 290 \text{ fs}$ and therefore multiples of 290 fs were used to excite the SET phase to coherently drive the vibrational amplitude beyond the threshold of transient structural change^{22,27–29} by the P_2 pulse. As shown in Fig. 3b, at $\Delta t = 290 \text{ fs}$ the original peak at 3.48 THz unexpectedly splits into two peaks, one ‘blue-shifts’ to 3.70 THz and an additional peak at 2.55 THz (labelled by \star) appears. The lower-frequency peak position shifts to higher frequency with increasing separation time Δt and gradually disappears after $\Delta t = 1,740 \text{ fs}$. By contrast, the peak at 3.70 THz observed in the excited state is very close to the frequency of the RESET phase

($\Omega_{\text{RESET}} = 3.74 \text{ THz}$; see Supplementary Fig. 2) and gradually red-shifts to 3.57 THz at $\Delta t = 1,740 \text{ fs}$. After the aforementioned pump-pump-probe experiment for $\Delta t = 6,090 \text{ fs}$, the coherent phonon spectra were taken at the same sample position without the prepump-pulse (P_1), confirming that the excited state reverts to the original frequency of the SET phase as the peak frequency is observed at the original frequency of 3.48 THz (Fig. 3c). Thus, the structural change observed in the photoexcited SET phase is reversible, but the excited crystal lattice exhibits a characteristic double-peak FT spectra on ultrafast timescales from $\Delta t = 290$ to $1,160 \text{ fs}$.

For the case of single-pulse excitation, different pre-translational dynamics are observed as shown in Fig. 3d. The FT spectra obtained from the time-domain data in Fig. 2b exhibit a peak frequency for the optical mode due to the Ge-Te bonds at 3.52 THz for the single pump fluence of 5.3 mJ cm^{-2} , while at 18.6 mJ cm^{-2} it red-shifts to 3.27 THz with a concomitant broadening of the peak structure. However, there is no frequency blue shift of the optical mode for the case of single- P_2 -pulse excitation, even if the single P_2 pump fluence exceeds the total fluence of the double pump-pulses (17.5 mJ cm^{-2} in Fig. 3b). This result indicates that the transient state characterized by the double-peak FT spectra is induced only by the coherent action of the optical phonon by virtue of the double pump-pulses.

Fluence dependence for the SET phase of iPCM. To check whether there is a threshold for the observation of the double-peak FT spectra in the SET phase of iPCM, we present the fluence dependence of a pump-pump-probe experiment for $\Delta t = 290 \text{ fs}$ for a fixed fluence ratio of P_1 and P_2 pulses (Fig. 4a). At the lowest fluence of $P_1 = 5.3 \text{ mJ cm}^{-2}$ and $P_2 = 3.5 \text{ mJ cm}^{-2}$ (8.8 mJ cm^{-2} in total), only a single phonon peak at $\approx 3.43 \text{ THz}$ was observed (Fig. 4b), which is the same peak position as that observed with only P_2 pulse excitation at 10.6 mJ cm^{-2} (see the bottom trace of Fig. 4b). On the contrary, for fluences higher than $P_1 = 10.6 \text{ mJ cm}^{-2}$ and $P_2 = 6.9 \text{ mJ cm}^{-2}$, the double-peak FT spectra emerge accompanied by a blue shift of the original peak. Thus, the choice of fluences $P_1 = 10.6 \text{ mJ cm}^{-2}$ and $P_2 = 6.9 \text{ mJ cm}^{-2}$ was made because of the lower threshold limit for the observation of the double-peak FT spectral feature in iPCM. As mentioned earlier, irradiation of the SET phase by a single P_2 pulse without P_1 irradiation cannot induce a transition into the transient double-peak coherent phonon spectra even if its fluence ($P_2 = 18.6 \text{ mJ cm}^{-2}$ in Fig. 3d) exceeds the combined fluence of a P_1 and P_2 pair above the threshold, the total fluence of $P_1 (10.6 \text{ mJ cm}^{-2}) + P_2 (6.9 \text{ mJ cm}^{-2}) = 17.5 \text{ mJ cm}^{-2}$ in Fig. 4. This finding demonstrates that the threshold for the appearance of the transient state is substantially decreased by irradiation with double pump-pulses or in all likelihood only double-pulse excitation can provide access to the transient state. It is also noted that the required pump fluence used here ($10\text{--}20 \text{ mJ cm}^{-2}$) is significantly lower than those used in the experiments using picosecond or nanosecond laser pulses, in which a fluence of $30\text{--}60 \text{ mJ cm}^{-2}$ for a 30-ps single pulse³⁰ or a fluence of $\approx 150 \text{ mJ cm}^{-2}$ for a 8-ns single pulse was applied³¹.

Transient reflectivity studies of other phases. In contrast to the pre-translational dynamics in the SET phase of iPCM, the phase transformation from the RESET phase of the iPCM was irreversible (Supplementary Note 1; Supplementary Figs 2–4). The carrier response suggests that the metastable state after irradiation of the RESET phase of iPCM by the P_1 pulse is different from that of the so-called laser-crystallized structure²⁶ (Supplementary Note 2; Supplementary Fig. 4), which should show a much different carrier response from the original phase. Note also that for the case of the polycrystalline (SET phase) GST

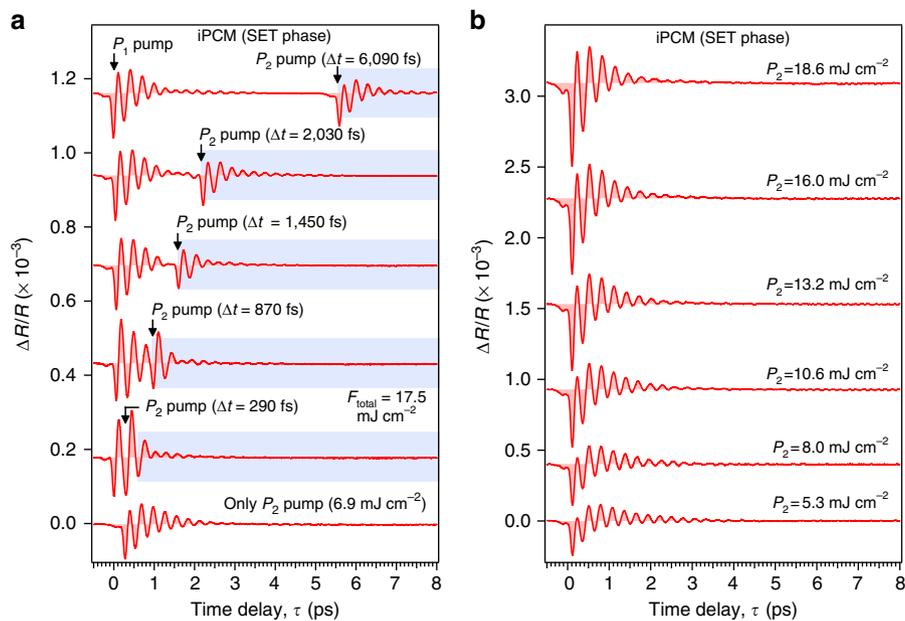

Figure 2 | Time-domain coherent phonon responses in photoexcited iPCM. (a) Transient reflectivity traces observed in the SET phase of an iPCM film for in-phase separation times between P_1 (10.6 mJ cm^{-2}) and P_2 (6.9 mJ cm^{-2}) pulses; $\Delta t = 290, 870, 1,450, 2,030$ and $6,090$ fs. The light-blue rectangles represent the coherent phonon signal used for monitoring the excited lattice, which were converted into FT spectra in Fig. 3b. The result for the case without the prepump (P_1) is shown at the bottom for reference. (b) Transient reflectivity traces observed in the SET phase of iPCM film at various pump fluences from 5.3 to 18.6 mJ cm^{-2} under the single-pulse excitation with only the P_2 pulse. The coherent phonon oscillations show longer relaxation dynamics at lower fluences, while they show shorter relaxation dynamics at higher fluences.

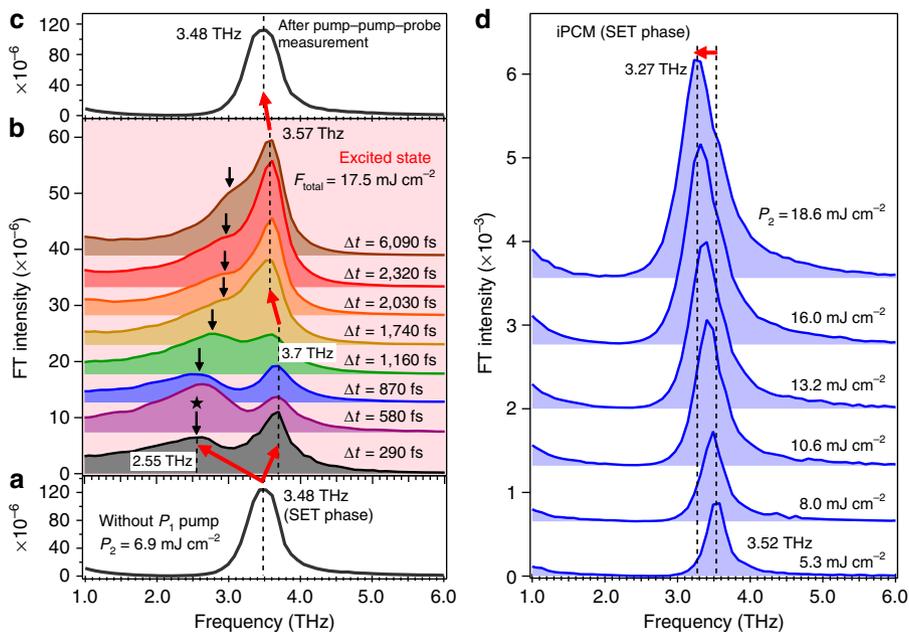

Figure 3 | Coherent phonon spectra in photoexcited iPCM. (a) FT spectrum in the SET phase monitored by weak pump ($P_2 = 6.9 \text{ mJ cm}^{-2}$) and probe ($P_3 = 0.2 \text{ mJ cm}^{-2}$) pulses without the prepump-pulse (P_1). The dotted line in **a** corresponds to the frequency of the optical mode in the SET phase ($\Omega_{\text{SET}} = 3.48 \text{ THz}$). (b) FT spectra obtained from the time-domain data in the excited state at various Δt as shown in Fig. 2a. The total fluence applied was $F_{\text{total}} = 17.5 \text{ mJ cm}^{-2}$. The red arrows show the split of the optical mode into doublet peaks at 3.7 and 2.55 THz at $\Delta t = 290$ fs. The dotted lines in **b** correspond to the dynamic shift of the 3.7 THz peak down to 3.57 THz at $\Delta t = 1,740$ fs. The black arrows point out the positions of a peak at 2.55 THz. (c) FT spectrum observed at the same spot after the measurement for $\Delta t = 6,090$ fs in **b** monitored without prepump (P_1). The dotted line in **c** is located at 3.48 THz, indicating the system reverts to the initial SET phase. (d) The FT spectra in the SET phase of iPCM obtained from the time-domain data in Fig. 2b. The peak frequency at 5.3 mJ cm^{-2} is 3.52 THz, while at the highest pump fluence of 18.6 mJ cm^{-2} it red-shifts to 3.27 THz as shown by the red arrow over the dotted lines.

alloy, no frequency blue shift (phonon hardening) was observed in the excited state under double-pump-pulse excitation, but only broadening and a red shift of the optical phonon mode was

observed on the timescale of a few picoseconds (Supplementary Note 3; Supplementary Fig. 5). Since photoexcited carriers in semiconductors relax via carrier-phonon scattering (inband

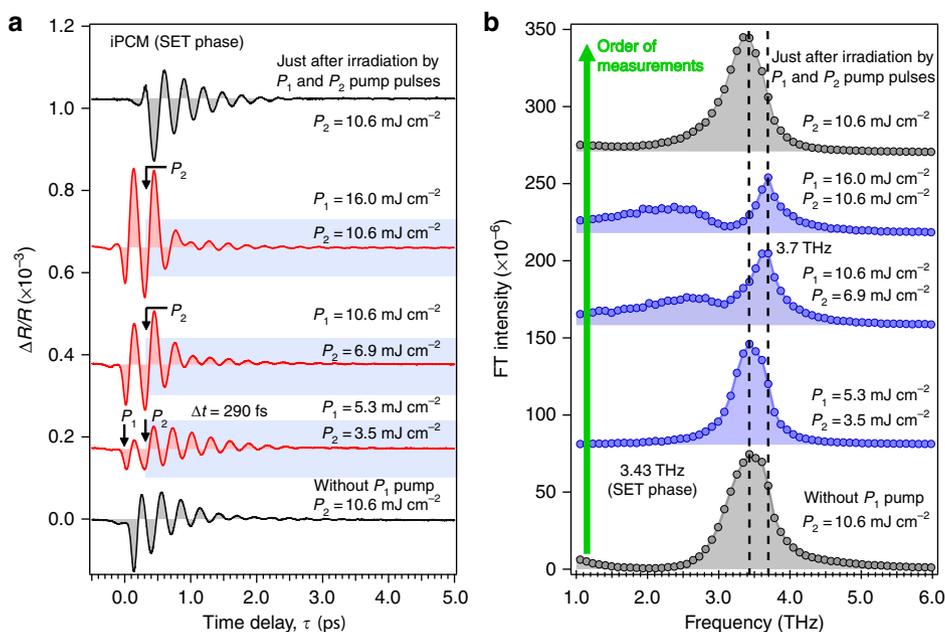

Figure 4 | Pump fluence dependence of pre-translational dynamics in the SET phase of iPCM. (a) Time-domain signal observed at various total pump fluences for a constant fluence ratio of the P_1 and P_2 pulses and for a fixed separation time of $\Delta t = 290 \text{ fs}$. The bottom trace was obtained using only the P_2 pump pulse before the series of the pump-pump-probe experiment with P_1 , P_2 and P_3 pulses, while the top trace was obtained immediately after the measurement of a pump-pump-probe experiment with $P_1 = 16 \text{ mJ cm}^{-2}$ and $P_2 = 10.6 \text{ mJ cm}^{-2}$. (b) The corresponding FT spectra obtained from the time-domain data in a. The single-peak frequency before the irradiation by the P_1 pulse is 3.43 THz. When the fluence was increased beyond $P_1 = 10.6 \text{ mJ cm}^{-2}$ and $P_2 = 6.9 \text{ mJ cm}^{-2}$ (17.5 mJ cm^{-2} in total), a double-peak structure appeared, accompanying by frequency blue-shift to $\approx 3.7 \text{ THz}$. The reversible process of these experiments was confirmed by the top trace, showing the peak position is nearly identical to that before exposure to the P_1 pulse. The dotted lines represent the position of the peaks at 3.43 and 3.7 THz, respectively.

relaxation) and trapping by defects in a few picoseconds³² (Supplementary Fig. 1), the observed frequency red shift is interpreted to be the result of phonon softening induced by electronic excitation²⁶. From the fact that for the polycrystalline GST alloy no frequency blue shift of the optical phonon was observed, it is concluded that the transient state cannot be accessed by the present double-pulse excitation.

Discussion

To discuss the pathways of pre-translational structural dynamics observed in the excited state, we consider the transient structure of iPCM in terms of its bonding nature^{7,33}. Given that $[\text{Ge}_2\text{Te}_2/\text{Sb}_2\text{Te}_3]_{20}$ iPCM sample has the same average composition as $\text{Ge}_2\text{Sb}_2\text{Te}_5$ (refs 7,14), we refer to a recent theoretical study based on an *ab initio* molecular dynamics simulation by Li *et al.*¹³, who reported that the phase transformation from the crystalline (SET) to amorphous (RESET) phase in GST alloy occurred over several picoseconds under optical excitation. The authors also claimed that the coordination number of Ge atoms changed from the original sixfold into a mixture of fivefold and fourfold coordination within 450 fs after the removal of 9% of the valence electrons in a GST alloy, followed by the further appearance of threefold coordination at 3 ps. On the other hand, Simpson *et al.*⁷ reported for the iPCM system, the presence of a lower coordination for Ge atoms, namely the possibility of fourfold or threefold coordination. These studies suggest that in the early stages of the non-thermal pre-phase transformation from the SET to RESET phases under repetitive photoexcitation by double pump-pulses, the bonding coordination around Ge atoms in the iPCM system is coherently modulated and becomes unstable giving rise to two different coordination environments (possibly fourfold and threefold⁷), providing a plausible explanation as to why a

double-peak spectral feature develops for the earlier time intervals of $\Delta t = 290$ – $1,160 \text{ fs}$ in Fig. 3b. In contrast to the case of strong photoexcitation by a single pump-pulse, hot-carrier injection on ultrafast timescales of several femtoseconds is suppressed and concurrently similar conditions to a mode-selective vibrational excitation³⁴ are established under double-pump-pulse excitation.

To conclude, we have experimentally explored the photoexcited state of GST phase-change materials, iPCM films, by comparison between the cases of single- and double-pulse excitation using pump-pump-probe femtosecond CPS far from equilibrium. A transient hidden phase characterized by double-peak FT spectra was uncovered for iPCM structures only when a double-pump-pulse sequence was applied, which is interpreted as being due to a mixture of two different Ge coordination environments, which relax within a few picoseconds. Our experimental results also demonstrate that the transition of the SET phase of iPCM to a hidden phase can be achieved with lower total energy using multiple pulse sequences than for the case of single-pulse excitation. These effects will provide a new route for faster and lower threshold phase switching with further testing of the iPCM SL structure. Thus, our finding of a non-thermal ultrafast pre-phase transformation in a iPCM film coupled with femtosecond multiple pulse sequences (Supplementary Fig. 6) or multiple terahertz light-pulse sequences³⁵ will provide highly relevant fundamental knowledge for ultrafast optical data processing³⁶ and for next-generation of ultra-high-speed phase-change random access memory (PCRAM).

Methods

Fabrication of GST SL (iPCM) films. Recently, Chong *et al.*⁵ proposed SL-like PCRAM considering the GST system as a composite of the pseudo-binary alloys, namely GeTe and Sb_2Te_3 alloys, with individual layers thick enough to maintain the characteristics of each composition. Both faster switching times ($< 5 \text{ ns}$) and lower programming currents were found for the SL-like PCRAM. More recently, motivated by the need to reduce both the switching speed and energy used, iPCM was

proposed. Tominaga *et al.*¹⁴ reported the fabrication of a GST SL (iPCM) based on the Ge flip-flop transition mechanism. Using iPCM structures designed from GeTe and Sb₂Te₃ layers, a few unit cells thick, they experimentally confirmed very low (only 12% compared with GST alloy films⁷) power operation of phase switching (SET ↔ RESET) in iPCM. The sample used in this paper was a thin film (20 nm thick) of a prototypical iPCM sample, [Ge₂Te₂/Sb₂Te₃]₂₀, which consisted of 20 repetitive sheet blocks from alternatively deposited 0.5-nm-thick GeTe and Sb₂Te₃ layers on a Si-(100) wafer using helicon-wave radio-frequency magnetron sputtering.

CPS using a pump-pump-probe sequence. CPS is a powerful tool to study the ultrafast dynamics of structural phase transitions occurring on ultrafast timescales. It has been applied to a wide variety of materials, such as semimetals and semiconductors^{22,25,28,37,38}, and Mott insulators¹⁹. In CPS, a pump pulse impulsively generates Raman-active collective atomic vibrations through light-matter coupling. We utilized a 40-fs amplified near-infrared optical pulse (800 nm; 1.55 eV and 100 kHz repetition rate) to excite and monitor coherent lattice vibrations in iPCM films after injection of photocarriers across the indirect bandgap of 0.5–0.7 eV (ref. 11). The optical penetration depth at 800 nm was estimated from the absorption coefficient to be ~20 nm, which matches the film thickness. The size of the probe beam after focusing was ~50% smaller than the pump, providing for negligibly small inhomogeneous excitation effects. The maximum photogenerated carrier density was estimated to be $n_{\text{exc}} \approx 5.1 \times 10^{21} \text{ cm}^{-3}$, induced by a single pump pulse with 10.6 mJ cm^{-2} , whose density corresponds to $\approx 2.9\%$ of the total number density of valence electrons ($n_{\text{tot}} \approx 1.76 \times 10^{23} \text{ cm}^{-3}$)³⁹. A train of two pump-pulses were generated through a Michelson-type interferometer, in which a motorized stage was installed under the mirrors to adjust the time interval (Δt) of the temporally separated pump-pulses. The ratio of the P_1 and P_2 pulses was set to 10:6.5 (i) to match the phonon amplitude of the initially excited phonon at $\tau = 0$ fs to that of the second excited phonon at separation times of $\Delta t = 290$ – 870 fs as was used in the previous study²⁸; in the present case, the amplitude of the phonon excited by a P_1 pulse at $\tau = 0$ fs decays to ≈ 65 – 70% in amplitude when $\Delta t = 290$ – 870 fs, and (ii) as it was characteristic of the 2-inch beam splitter with a p -polarized incident pump beam. The photoinduced reflectivity change ($\Delta R/R$) was recorded as a function of the time delay (τ) between the pump and probe pulses. The delay was scanned over 10 ps and averaged for 1,000 scans using an oscillating retroreflector with a 10-Hz scan frequency.

Acknowledgements

This work was supported by the X-ray Free Electron Laser Priority Strategy Program (Nos 12013011 and 12013023) from the Ministry of Education, Culture, Sports, Science and Technology of Japan), and by CREST, Japan Science and Technology Agency.

Author contributions

M.H. and J.T. planned and organized this project. J.T. fabricated the sample. M.H. performed experiments and analysed the data. M.H., P.F., K.M., A.V.K. and J.T. discussed the results. M.H. and P.F. co-wrote the manuscript.
