(Received 19 March 2001; published 11 July 2001)

For melt-spun amorphous (a-Cu₅₀Ti₅₀) and a-Pd₈₀Si₂₀, crystallization under electropulsing was studied by means of the discharge of a condenser with initial current density \( i_{\text{d0}} \) of the order of \( 10^7 \) A/m² and decay time \( \tau \) in between 2 and 0.1 ms, where a specimen was sandwiched by AlN/BN substrates to minimize an effect of joule heating. The crystallization proceeds during electropulsing when \( i_d \) is higher than the threshold \( i_{\text{d0,c}} \). Here \( i_{\text{d0,c}} \) is a function of \( \tau \) and shows a minimum value of \( 1.4 \times 10^7 \) A/m² at \( \tau \approx 2 \) ms for a-Cu₅₀Ti₅₀ and \( 2.6 \times 10^7 \) A/m² at \( \tau \approx 0.9 \) ms for a-Pd₈₀Si₂₀, where the maximum increase in temperature during electropulsing is about 120 K for a-Cu₅₀Ti₅₀ and 50 K for a-Pd₈₀Si₂₀, respectively. One-half of the specimen volume crystallizes after a few repetitions of electropulsing with \( i_{\text{d0}} \) beyond \( i_{\text{d0,c}} \) for a-Cu₅₀Ti₅₀ and after several repetitions for a-Pd₈₀Si₂₀. We surmise that for the density fluctuations existing in amorphous alloys, under electropulsing a high-density region undergoes a resonant collective motion as a whole, which induces migrational motions of atoms in the low-density matrix around it. For a-Pd₈₀Si₂₀, it is observed that an unknown phase was formed in the early stage of the crystallization under electropulsing and disappeared after further electropulsing. It is also found for a-Cu₅₀Ti₅₀ and a-Pd₈₀Si₂₀ that for electropulsing with high \( i_{\text{d0}} \), the electrical resistivity of a specimen decreased at the early stage of the crystallization and then turned to increase for further electropulsing. These phenomena may be associated with changes in the thermodynamic free energy of phases under an electric current predicted by the theoretical works. We surmise that present electropulsing excites a resonant collective motion of many atoms and modifies the thermodynamic free energy of phases too.

I. INTRODUCTION

The recent review for effects of an electric current on the solid-state phase transformation in metals reports that various significant effects depending on subjects have been found in both crystalline and amorphous metals.¹ For amorphous alloys, a dc electric current of \( 10^7 \) A/m² causes a decrease in the crystallization temperature by 10–20 K for various melt-spun amorphous (a) alloys.²–⁷ Repetition of electropulsing with a duration of 60–100 μs and a peak current density of \( 10^8 \) A/m² brings about a decrease in the crystallization temperature by 150–170 K for a-Fe-Si-B alloys.⁸–¹² Both the effects of a dc electric current and repetition of electropulsing may be similar to each other after taking into account difference in the current density and the total time for passing current. The effects are much greater than can be explained by simple electromigration theory and suggest the enhancement of an electromigration effect through a collective motion of many atoms.¹³–¹⁵ Recent theoretical works on the thermodynamic effect of an electric current on the phase transformation in amorphous alloys report that metastable phases can manifest under influence of an electric current¹³,¹⁴ or nanocrystalline growth may be a function of the current density.¹⁵ However, present experimental knowledge is very poor for examination of the theoretical works. On the other hand, the probable enhancement of atomic migration associated with a collective motion of many atoms is not taken into account in the theoretical works.

Meanwhile, the peculiar frequency dependence of Young’s modulus is found in the frequency range between 10 and \( 10^3 \) Hz for a-Pd₈₀Si₂₀.¹⁶ It is found that Young’s modulus observed in vibrating reed measurements at a strain amplitude of \( 10^{-6} \) reveals a deviatory decrease from that observed in quasistatic tensile tests showing a minimum at around \( 10^2 \) Hz. On the other hand, it is known that Young’s modulus observed in quasistatic tensile tests is lower by 20%–40% for amorphous alloys than for the corresponding crystalline counterparts,¹⁷–⁶ indicating that the fractional ratio of constituent anelastic strain to the total strain is much larger in amorphous alloys than in the crystalline counterparts. The fractional ratio of constituent anelastic strain is expected to decrease with increasing frequency except when a resonant anelastic process is excited and increases the anelastic strain. Since a decrease in Young’s modulus indicates an increase in the fractional ratio of constituent anelastic strain, the peculiar frequency dependence of Young’s modulus found for a-Pd₈₀Si₂₀ suggests that a certain resonant anelastic process is excited in the frequency range between 10 and \( 10^3 \) Hz, mainly at around \( 10^2 \) Hz. The decrease in Young’s modulus found at around \( 10^2 \) Hz is as large as 10%–30%¹⁶, suggesting that a considerable fraction of atoms in a specimen are associated with the resonant anelastic process. These results may suggest that collective motion of many atoms can be excited as resonant motion as a whole.

Further, the characteristic strain amplitude dependence of Young’s modulus is observed at around \( 10^2 \) Hz for a-Pd₈₀Si₂₀. It is found that Young’s modulus observed in vibrating reed measurements at around \( 10^2 \) Hz shows a strong increase with increasing strain amplitude, suggesting...
that a displacement amplitude of a probable resonant collective motion of many atoms tends to show saturation with increasing strain amplitude. The characteristic strain amplitude dependence of Young’s modulus found at around $10^2$ Hz is commonly observed for $\alpha$-Cu$_{50}$Ti$_{50}$ (Refs. 21 and 22) and $\alpha$-Cu$_{50}$Zr$_{50}$ (Ref. 23). Then one can suppose the density fluctuations existing in amorphous alloys where the high-density regions are embedded in the low-density matrix and that migrational motions of atoms in the low-density matrix can be induced when the high-density region undergoes a collective motion as a whole. For such a case, one can expect that enhancement of atomic migration under passing electric current in amorphous alloys is increased when resonant collective motion of many atoms can be excited.

In this case, how to excite such a resonant collective motion of many atoms intensively may be important to pursue experimentally the underlying mechanism for the crystallization of amorphous alloys under the influence of an electric current. After these considerations, we carried out the preliminary works $^{24,25}$ for the crystallization of $\alpha$-Pd$_{80}$Si$_{20}$ due to electropulsing by means of the discharge of a condenser. The current density $i_d$ during electropulsing decays with increasing elapsed time $t$ as

$$i_d = i_{d0} \exp(-t/\tau),$$

where $i_{d0}$ denotes $i_d$ at the start of electropulsing and $\tau$ the decay time of discharge. On the other hand, it is known that a Debye peak shows a maximum at $2\pi f'\tau' = 1$, where $\tau'$ is the relaxation time of a relaxation process and $f'$ a measurement frequency. As a first attempt, we tried electropulsing with $\tau$ of the order of 1 ms for $\alpha$-Pd$_{80}$Si$_{20}$, where we supposed that the value of $\tau$ to excite a resonant collective motion suggested after the peculiar frequency dependence of Young’s modulus is the order of $1/(2\pi f')$ with $f'$ being the order of $10^2$ Hz. In preliminary works, we found that the crystallization of $\alpha$-Pd$_{80}$Si$_{20}$ due to electropulsing takes place when $i_{d0}$ is the order of $10^8$ A/m$^2$, and a maximum temperature attained during electropulsing appears to be much lower than the crystallization temperature observed during the conventional heating measurement. In order to pursue further experimental knowledge, we investigated the crystallization of $\alpha$-Pd$_{80}$Si$_{20}$ under electropulsing as well as crystallization under electropulsing in $\alpha$-Cu$_{50}$Ti$_{50}$ for which effects of a dc electric current on the crystallization were already reported. $^{2-5}$

II. EXPERIMENT

Amorphous ($\alpha$-)Cu$_{50}$Ti$_{50}$ and $\alpha$-Pd$_{80}$Si$_{20}$ were prepared as thin tapes by melt spinning in a high-purity Ar gas atmosphere. Specimens were cut out from the amorphous alloy thin tapes. Both surfaces of a specimen were smoothed by polishing mechanically using fine emery paper in water avoiding heat-up during polishing. The thickness and width of specimens after polishing were about 20 $\mu$m and 0.8 mm for $\alpha$-Cu$_{50}$Ti$_{50}$ specimens and about 25 $\mu$m and 0.9 mm for $\alpha$-Pd$_{80}$Si$_{20}$ specimens, respectively.

Figure 1(a) shows schematic drawing for the specimen setup, where a specimen is sandwiched by two aluminum nitride (AIN)/boron nitride (BN) composite substrates and they are fastened as a whole by three spring clamps. It is noted that the thermal conductivity, 90 W/K/m, of the AIN/BN substrates is as high as 83.5 W/K/m of iron. Figure 1(b) is a schematic drawing of the AIN/BN upper substrate A, where four copper electrodes are embedded in the bottom side. The gauge length between current electrodes $I_1$ and $I_2$ and that between potential electrodes $V_1$ and $V_2$ are 50 and 25 mm for most cases, respectively. Figure 1(c) shows the lower AIN/BN substrate $B_1$, which is used for measurements of changes in the resistivity $R$ due to electropulsing. Figure 1(d) shows the lower AIN/BN substrate $B_2$, which is used for temperature measurements during electropulsing, where Almel and Chromel thermocouple wires 25 $\mu$m in diameter are embedded in the thin channel on the top side. It is noted that the junction head of the thermocouple directly contacts the specimen surface during temperature measurements. In order to ensure good thermal contact between the specimen and AIN/BN substrates, the bottom surface of the upper substrate A and the top surfaces of the lower substrates $B_1$ and $B_2$ are smoothed by polishing mechanically.

Figure 2 shows the measurement setup for electropulsing which can be made by discharge of a condenser. The decay time $\tau$ used in the present work was in between 0.1 and 2.5 ms. The resistivity measurements were conducted by a four-probe method after every electropulsing, where an interval between electropulsings was several minutes. It is noted that the resistivity measurements were made by passing a dc elec-
tric current with $10^6 \text{ A/m}^2$ where no influences on the crystallization were expected. Separately, measurements of the specimen temperature during electropulsing were carried out, where the thermoelectric power was measured by using a preamplifier and a high-speed analog-to-digital converter.

As already mentioned, $i_{d0}$ and $t$ in Eq. (1) may be key parameters for the crystallization under electropulsing. We measured changes in $R$ at 300 K after electropulsing, where $i_{d0}$ was increased stepwise. The $R/R_0$ vs $i_{d0}$ data were compiled for various $t$, where $R_0$ denotes $R$ at 300 K in the as-quenched state. On the other hand, since the electric energy of a pulse given to the unit volume of a specimen, $P_d$, is indicative of joule heating, the $R/R_0$ vs $P_d$ plots are also shown after the $R/R_0$ vs $i_{d0}$ data.

We also carried out resistivity measurements during heating at a constant rate in vacuum by using an electric furnace (furnace heating, hereafter). Thin gold wires were spot-welded to a specimen as current and potential lead wires, and then the specimens with lead wires and thin thermocouple wires were put into a quartz glass tube as a whole. During the furnace heating measurements, the quartz glass tube was evacuated to $10^{-4} \text{ Pa}$, where AlN/BN substrates were not used and electropulsing was not made. For $a$-Pd$_{80}$Si$_{20}$, probable effects of rapid heating, magnetic field, and tensile stress on the crystallization process were studied too. The measurement setup for the rapid heating was similar to that of the furnace heating except that light exposure heating was made instead of furnace heating. The measurement setup for furnace heating under tensile stress was similar to that of furnace heating except that a specimen was tensed by a spring through a thin stainless steel wire. The effect of a magnetic field was studied for crystallization under electropulsing, where the measurement setup was similar to Fig. 1(a) except that the AlN/BN substrates A and B1 were further sandwiched by permanent magnets.

X-ray diffraction (XRD) measurements were made by the $\theta$-2$\theta$ scan using Cu K$\alpha$ radiation, where reflections from Si powder put on a specimen surface were used as reference.

### III. RESULTS AND DISCUSSION

#### A. $a$-Cu$_{50}$Ti$_{50}$

Figure 3 shows examples of changes in $R$ observed for $a$-Cu$_{50}$Ti$_{50}$ specimens during furnace heating. It is known that $a$-Cu$_{50}$Ti$_{50}$ crystallizes to crystalline CuTi (Ref. 26) in one step as seen in Fig. 3. The onset temperature of crystallization, $T_x$, found in Fig. 3 is 626 K at the heating rate of 0.08 K/s and 646 K at 0.3 K/s, respectively, which show good agreement with $T_x$ reported for $a$-Cu$_{50}$Ti$_{50}$ (Ref. 27) after taking into account the difference in the heating rate. The decrease in $R$ at 300 K observed after crystallization, $(\Delta R/R_0)_x$, is $-0.8$.

Figure 4(a) shows an example of the $R/R_0$ vs $P_d$ plot observed for an $a$-Cu$_{50}$Ti$_{50}$ specimen after electropulsing with $\tau = 1.2 \text{ ms}$, where $R/R_0$ decreases to about 0.84 in one
The maximum decrease in $D_{\text{max}}$ increased rapidly, showing a maximum at about 2.5 ms. Figure 5 shows examples of the max-$D_{\text{max}}$ vs $i_d$ data observed for various $\tau$ values. The threshold value of $i_d$ observed for the specimens with $\tau \sim 0.2$ ms are due to a decreased gauge length for the $R$ measurements used.

Step after electropulsing with $P_d = 3.4 \text{ J/mm}^3$. Figure 4(b) shows an example of changes in the specimen temperature, $\Delta T_{\text{ep}}$, observed during electropulsing with $\tau = 1.1$ ms and $P_d = 3.4 \text{ J/mm}^3$. After the start of electropulsing, $\Delta T_{\text{ep}}$ increased rapidly, showing a maximum at about 2.5 ms (max-$\Delta T_{\text{ep}}$, hereafter) and then decreased steeply. The max-$\Delta T_{\text{ep}}$ found is about 150 K for $P_d = 3.4 \text{ J/mm}^3$, i.e., the maximum specimen temperature attained is about 450 K. Figure 4(c) shows examples of the max-$\Delta T_{\text{ep}}$ vs $P_d$ data, where max-$\Delta T_{\text{ep}}$ increases linearly with $P_d$.

Figure 5(a) is similar to Fig. 4(a), but here the $R/R_0$ vs $P_d$ data observed for various $\tau$ are shown. The threshold value of $P_d$, $P_{d,c}$, at which $R/R_0$ starts to show a strong decrease reveals a minimum value of about 2.9 J/mm$^3$ at $\tau = 1$ ms in the present range between 0.2 and 2 ms, indicating that joule heating plays a minor role for the crystallization under electropulsing. It is noted that the max-$\Delta T_{\text{ep}}$ of about 120 K at $P_d$ of 2.9 J/mm$^3$ may be found from the max-$\Delta T_{\text{ep}}$ vs $P_d$ plot shown in Fig. 4(c); i.e., the maximum specimen temperature attained is about 420 K at $P_d$ of 2.9 J/mm$^3$. Figure 5(b) is a redraw of Fig. 5(a), but here $R/R_0$ is plotted against $i_d$. The threshold value of $i_{d,0}$, at which $R/R_0$ starts to show a strong decrease appears to show a minimum value of about $1.4 \times 10^5 \text{ A/m}^2$ at $\tau$ in between 1 and 2 ms, indicating that the decay time of electropulsing plays an important role in crystallization under electropulsing. For $a$-$Cu_{50}Ti_{50}$ specimens, the maximum decrease in $(\Delta R/R_0)/|\Delta R/R_0|_0$, attained is about $-0.5$. Such a strong decrease in $(\Delta R/R_0)/|\Delta R/R_0|_0$ took place in a few repetitions of electropulsing with $\tau$ of about 1–2 ms or in several repetitions of electropulsing with $\tau$ of about 0.2 ms. It is suggested that intensive atomic migration takes place during electropulsing with $i_{d,0}$ beyond $i_{d,0,c}$ and their magnitude is a function of $\tau$. It is noted that an increase in $R$ following a decrease in $R$ due to electropulsing is found at high $i_{d,0}$ beyond $7 \times 10^5 \text{ A/m}^2$ for electropulsing with $\tau$ of about 0.2 ms. As already mentioned, recent theoretical work on crystallization under electropulsing suggests that nanocrystalline precipitates formed by electropulsing can shrink when the current density is increased beyond a certain threshold value. The increase in $R/R_0$ observed at high $i_{d,0}$ can possibly be explained by the predicted reverse effect of electropulsing at a high current density.

Figure 6 shows the XRD spectra observed for various $a$-$Cu_{50}Ti_{50}$ specimens. The XRD spectrum 1 observed for the as-quenched state shows a broad XRD peak. The XRD spectrum 4 observed after the furnace heating to 700 K shows good agreement with that expected for crystalline CuTi. The XRD spectrum 2 was observed for the specimen which showed a decrease in $R$ by 25% in $R/R_0$ due to electropulsing. The XRD spectrum 3 was observed for the specimen which was first subjected to electropulsing with a decrease in $R$ by 19% in $R/R_0$ and then to the furnace heating to 700 K. The XRD spectrum 2 is composed of the crystalline CuTi XRD peaks and the broad XRD peak from $a$-$Cu_{50}Ti_{50}$, indicating that the decrease in $R$ due to electropulsing is associated with crystallization. The XRD spectrum 3 is very similar to the XRD spectrum 4 except that the XRD peaks at about 41.2° and 42.2° in 2θ are broader by about 20% than those seen in the XRD spectrum 4. This result indicates that the mean grain size is smaller in the specimen subjected to electropulsing first than in the specimen subjected to furnace heating alone. In other words, the homogeneous nucleation process can be accelerated under electropulsing.
In order to compare the crystallization under electropulsing and the thermally activated crystallization, the time-temperature-transformation (TTT) diagram\textsuperscript{28-30} will be visited below. The Johnson-Mehl-Avrami equation\textsuperscript{31,32} gives the volume fraction $X$ of crystallization products as (for the case of small $X$)

$$
X = \left(\frac{\pi}{6}\right) I_n u_c^3 t^4,
$$

where $I_n$ denotes the nucleation rate and $u_c$ the crystal growth rate. The homogeneous nucleation rate may be given by\textsuperscript{28,29}

$$
I_n = N_e \nu \exp(-Q),
$$

where $N_e$ is the number of single molecules per unit volume and $Q$ is given by

$$
Q = \alpha d(T^3 - T_r^3),
$$

In Eq. (4), $T_r$ is the reduced temperature given by $T/T_m$ and $\Delta T_r$ the reduced undercooling denoted by $(T_m - T)/T_m$, where $T_m$ denotes the melting temperature. $\alpha$ measures the free energy $\Delta G^*$ of forming the critical nucleus, e.g., $\alpha = 1.024$, when one takes $\Delta G^* = 50kT$ at $\Delta T_r = 0.2$.\textsuperscript{28,29} In Eq. (3), the frequency factor $\nu$ is given by\textsuperscript{28,29}

$$
\nu = kT/(3 \pi a_0^3 \eta),
$$

where $a_0$ is the mean atomic or ionic diameter for the diffusive jump and the viscosity $\eta$ may be given by the Fulcher-type equation\textsuperscript{33}

$$
\eta = A \exp\left[B/(T - T_0)\right],
$$

where $A$, $B$, and $T_0$ are constants. In Eq. (2), $u_c$ may be given by\textsuperscript{28,29}

$$
u_c = (\phi D_g/a_0)\left[1 - \exp(-\Delta H_{fm}/kT)\right],
$$

where $D_g$ is a diffusion coefficient for atomic motion required for crystal growth, $\Delta H_{fm}$ the latent heat of fusion, and $\phi$ the fraction of sites at the interface where atoms can preferentially be added. The critical cooling rate for glass formation, $\beta_c$, approximated for the linear cooling curve required to avoid the nose of the TTT curve for crystallization may be given by\textsuperscript{34}

$$
\beta_c = (T_m - T_n)/t_n,
$$

where $T_n$ and $t_n$ are the temperature and time corresponding to the nose of the TTT curve, respectively.

Figure 7 shows the TTT diagram for $a$-Cu$_{50}$Ti$_{50}$, where plotted are the incubation time $t_x$ for the crystallization found in isothermal annealing\textsuperscript{6} and $T_x$ found during heating at a constant rate $\gamma$ under the assumption that $20 K/\gamma$ corresponds to $t_x$ in isothermal annealing at $T_x$. In Fig. 7, a redrawing of the $T$ vs $t$ data observed during electropulsing with $P_d = 3.4 \text{kJ/mm}^2$ [see Fig. 4(b)] is shown too. The TTT curve has been estimated as follows. The heat of crystallization of 17.2 kJ/mol reported for $a$-Cu$_{50}$Ti$_{50}$ (Ref. 35) is assumed to be $\Delta H_{fm}$ in Eq. (7). Here $\beta_c$ in Eq. (8) is estimated to be about 1600 K/s after the DTA data for $a$-Cu$_{50}$Ti$_{50}$ (Ref. 27) and the relationship between $\beta_c$ and $(T_x - T_r)$ reported,\textsuperscript{36} where $T_r$ is the glass transition temperature. $A$ and $B$ in Eq. (6) are assumed to be the same to $A = 3.8 \times 10^{-4}$ Pa s and $B = 1975$ K observed for $a$-Pd$_{84}$Si$_{16}$.\textsuperscript{37} Here $\phi D_g$ in Eq. (7) is assumed to be $1 \times 10^{-4} \exp(-H_g/kT)$ [m$^2$ s$^{-1}$], where $H_g$ is the activation enthalpy for diffusion. The TTT curve shown in Fig. 7 is found to explain the $t_x$ and $T_x$ data and $\beta_c$ after assuming $\Delta G^* = 72kT$ at $\Delta T_r = 0.2$ for Eq. (4), $T_0 = 470$ K in Eq. (6), and $H_g = 1.32$ eV, which may be not unreasonable. After the TTT curve and the $T$ vs $t$ data observed during electropulsing, one can say that crystallization under electropulsing cannot be explained by the thermal excitation process alone. This issue will be discussed later on.

**B. $a$-Pd$_{80}$Si$_{20}$**

Figure 8 shows an example of the $R$ vs $T$ data observed for an $a$-Pd$_{80}$Si$_{20}$ specimen during furnace heating, where $T_x$ found is about 680 K for a heating rate of 0.2 K/s and $(\Delta R/R_0)_1$ at 300 K is $-0.6$. The $R$ vs $T$ data are very similar to that reported\textsuperscript{38} after taking into an account the difference in

![FIG. 7. The TTT diagram for $a$-Cu$_{50}$Ti$_{50}$ Curve 1 is a redrawing of the $T$ vs $t$ data shown in Fig. 4(b). The open circles 2 denote the incubation time $t_x$ for crystallization found in isothermal annealing (Ref. 6) and the solid triangles 2’ denote $T_x$ found in the constant heating rate ($\gamma$) measurements under the assumption of $t_x = 20$ K/$\gamma$. The horizontal dashed line denotes $T_m$. See text for the TTT curve.](image)

![FIG. 8. Resistivity changes observed for an $a$-Pd$_{80}$Si$_{20}$ specimen during the furnace heating with the heating rate of about 0.2 K/s.](image)
the heating rate. Figure 9(a) shows an example of the $R/R_0$ vs $P_d$ plot observed for an $a$-Pd$_{80}$Si$_{20}$ specimen after electropulsing with $\tau = 0.4$ ms. Figure 9(b) shows an example of changes in the specimen temperature $\Delta T_{ep}$ observed during electropulsing with $\tau = 0.4$ ms and $P_d = 2.2$ J/mm$^3$. After the start of electropulsing, $\Delta T_{ep}$ increased rapidly, showing a maximum at about 1.5 ms and then decreased steeply. The max-$\Delta T_{ep}$ found is about 50 K for $P_d = 2.2$ J/mm$^3$, i.e., the maximum specimen temperature attained is about 350 K at $P_d$ of 2.2 J/mm$^3$. Figure 9(c) shows examples for the max-$\Delta T_{ep}$ vs $P_d$ data, where max-$\Delta T_{ep}$ increases linearly with $P_d$ in the present experimental range.

Figures 10(a) and 10(b) are similar to Figs. 5(a) and 5(b), but here the $R/R_0$ vs $P_d$ plot and the $R/R_0$ vs $i_{d0}$ data observed for various $\tau$ observed for $a$-Pd$_{80}$Si$_{20}$ are shown, respectively. $P_d$ shows a minimum value of about 2.0 J/mm$^3$ at $\tau \sim 0.5$ ms in the present $\tau$ range between 0.1 and 1.4 ms, indicating that joule heating plays a minor role for crystallization under electropulsing. It is noted that the max-$\Delta T_{ep}$ of about 50 K at $P_d$ of 2.0 J/mm$^3$ may be found from the max-$\Delta T_{ep}$ vs $P_d$ plot shown in Fig. 9(c); i.e., the maximum specimen temperature attained is about 350 K at $P_d$ of 2.0 J/mm$^3$. Here $i_{d0}$ is a function of $\tau$ and appears to show a minimum value of about $2.6 \times 10^9$ A/m$^2$ at $\tau$ between 0.5 and 1.4 ms indicating that the decay time of electropulsing plays an important role on the crystallization under electropulsing.

Figure 11 is similar to Fig. 6, but here the XRD spectra observed for $a$-Pd$_{80}$Si$_{20}$ specimens are shown. The XRD spectrum 1 was observed for the specimen after furnace heating to 800 K. The XRD spectrum 2 was found for the specimen which showed a decrease in $R$ by 6.2% in $R/R_0$ after electropulsing. The XRD spectra 3–7 were observed for the specimens which were first subjected to electropulsing to various extents for decreases in $R$ and then to furnace heating to 800 K. The XRD spectrum 1 is very similar to that reported.38–42 The XRD peak from an amorphous phase, the XRD peaks being similar to those seen in the XRD spectrum 1 and the unknown XRD peak at about 41° in 2 $\theta$ indicated by the vertical arrow in Fig. 11 (the 41° XRD peak). The XRD peaks in the XRD spectrum 2 are much broader than the corre-
After rapid heating to about 800 K with a heating rate of 130 K/s, the XRD spectrum 8 was observed for the a-Pd$_{80}$Si$_{20}$ specimen subjected to rapid heating to 800 K following electropulsing under a magnetic field of about 0.5 T. The XRD peaks in the XRD spectrum 1, indicating that the size of crystallites is much smaller for crystallization due to electropulsing than for crystallization attained during furnace heating to 800 K. For the XRD spectrum 3 which was observed after furnace heating to 800 K following the XRD spectrum 2, the XRD peaks became to be sharper than those found in the XRD spectrum 2, but were broader than those observed in the XRD spectrum 1, suggesting that the homogeneous nucleation process is enhanced by electropulsing. The 41° XRD peak became stronger in the XRD spectrum 3 than in the XRD spectrum 2, suggesting that the unknown phase responsible for the 41° XRD peak is stable below 800 K. On the other hand, the XRD spectra 4 – 7 indicate that the size of crystallites is much smaller after rapid heating than after furnace heating. The 41° XRD peak was not detected for the XRD spectrum 8. The XRD spectrum 9 is very similar to the XRD spectrum 8 except that the XRD peaks are broader in the XRD spectrum 8 than in the XRD spectrum 1, suggesting that the mean grain size of crystallites is smaller after rapid heating than after furnace heating. The 41° XRD peak was not detected for the XRD spectrum 8. The XRD spectrum 9 is very similar to the XRD spectrum 5 suggesting that the magnetic field associated with electropulsing is not responsible for the manifestation of the unknown phase formed in the early stage of crystallization due to electropulsing.

Recently, it has been found that an electric current may induce internal stress in amorphous alloys.$^{6,43,44}$ On the other hand, it is reported that the incubation time for crystallization of a-Pd$_{80}$Si$_{20}$ to the metastable solid solution (SS) becomes shorter under a tensile stress of about 400 MPa, where isostructural annealing has been made in the temperature range between 520 and 400 K.$^{45,46}$ However, no reports are found for a probable effect of tensile stress on the crystallization of a-Pd$_{80}$Si$_{20}$ to the stable phases (see Figs. 8 and 11), which may be accelerated by electropulsing. Then we carried out furnace heating measurements under tensile stress, where electropulsing was not made. Figure 13 shows changes in $R$ observed for the a-Pd$_{80}$Si$_{20}$ specimens during furnace heating with a heating rate of 0.4 K/s under various tensile stresses below 522 MPa. All specimens showed an increase in $R$ due to creep deformation and failed at around 650 K. Since the specimen was tensed by a spring, one-half of the specimen was pulled out from the furnace region immediately after its failure. No crystallization was detected by the XRD measurement of the pulled-out specimen (not shown here), indicating that the lower bound of the crystallization of a-Pd$_{80}$Si$_{20}$ to stable phases under a tensile stress of 522 MPa is about 650 K for a heating rate of 0.4 K/s.

Figure 14 shows the TTT diagram of a-Pd$_{80}$Si$_{20}$ reported.$^{38,39,45,46}$ In Fig. 14, the symbols 2 denote $T_x$, found in the present constant heating rate ($\gamma$) measurements, where we assume that 20 K/γ corresponds to $T_x$ for isothermal an-
nealing at \( T_x \) after the isothermal annealing data reported. The dashed line 2′ denotes the lower bound of the crystallization of \( \alpha\text{-Pd}_{80}\text{Si}_{20} \) to stable phases under a tensile stress of about 500 MPa, where \( t_x = 20 \text{ K}/\gamma \) is assumed. The \( T \) vs \( t \) data 1 are a redrawing of Fig. 9.

The TTT curve has been estimated as follows: The heat of crystallization of 467 J/mol reported for \( \alpha\text{-Pd}_{80}\text{Si}_{20} \) (Ref. 37) is assumed to be \( \Delta H_{fm} \) in Eq. (7). Here \( \beta \) in Eq. (8) is assumed to be 2500 K/s reported for \( \alpha\text{-Pd}_{80}\text{Si}_{20} \). \( A \) and \( B \) in Eq. (6) are assumed to be the same to \( A = 3.8 \times 10^{-4} \text{ Pa s} \) and \( B = 1975 \text{ K} \) observed for \( \alpha\text{-Pd}_{80}\text{Si}_{16} \). Here \( \phi D_x^0 \) in Eq. (7) is assumed to be \( 1 \times 10^{-4} \exp(-H_x/kT) \text{ [m}^2 \text{s}^{-1}] \). The TTT curve shown in Fig. 14 is found to explain the \( t_x \) and \( T_x \) data and \( \beta \), after assuming \( \Delta G^\theta = 25kT \) at \( \Delta T_r = 0.2 \) for Eq. (4). \( T_0 = 551 \text{ K} \) in Eq. (6), and \( H_x = 1.84 \text{ eV} \). After the TTT curve and the \( T \) vs \( t \) data observed during electropulsing, one can say that crystallization under electropulsing cannot be explained by the thermal excitation process alone as well as that in \( \alpha\text{-Cu}_{50}\text{Ti}_{50} \).

**C. Crystallization under electropulsing**

The \( R/R_0 \) vs \( P_d \) data shown in Figs. 5(a) and 10(a) indicate that \( P_{d,c} \) is function of \( \tau \), suggesting that joule heating plays a minor role on crystallization under electropulsing. The max-\( \Delta T_{ep} \) vs \( t \) data shown in Figs. 4(c) and 9(c) indicate that the maximum temperature attained during electropulsing with \( \tau \) of the order of 1 ms at the onset of crystallization is about 420 K for \( \alpha\text{-Cu}_{50}\text{Ti}_{50} \) and about 350 K for \( \alpha\text{-Pd}_{80}\text{Si}_{20} \), respectively. It is suggested that crystallization under electropulsing cannot be explained by the thermal activation process alone for both \( \alpha\text{-Cu}_{50}\text{Ti}_{50} \) and \( \alpha\text{-Pd}_{80}\text{Si}_{20} \).

After the \( (R/R_0)_{300K} \) vs \( i_{d0} \) data shown in Figs. 5(b) and 10(b), we defined the threshold \( i_{d0,c} \) for crystallization under electropulsing as \( i_{d0} \) found at \( (R/R_0)_{300K} = 0.95 \). In Fig. 15, \( i_{d0,c} \) is plotted against \( \tau \). As already mentioned, \( i_{d0,c} \) is a function of \( \tau \), where \( i_{d0,c} \) appears to show a minimum value of \( 1.4 \times 10^9 \text{ A/m}^2 \) at \( \tau \approx 2 \text{ ms} \) for \( \alpha\text{-Cu}_{50}\text{Ti}_{50} \) and 2.6 \( \times 10^9 \text{ A/m}^2 \), at \( \tau \approx 0.9 \text{ ms} \) for \( \alpha\text{-Pd}_{80}\text{Si}_{20} \), respectively. This result may support the idea of density fluctuations existing in amorphous alloys mentioned above: i.e., under electropulsing, a high density region undergoes a resonant collective motion as a whole which induces migrational motions of atoms in the low-density matrix around it. The assumption that the resonant frequency \( f' \) of collective motion is the order of \( 1/(2\pi\tau) \) may give \( f' \) of the order of 10^2 Hz for \( \tau \approx 2 \text{ ms} \) for \( \alpha\text{-Cu}_{50}\text{Ti}_{50} \) and \( \tau \approx 0.9 \text{ ms} \) for \( \alpha\text{-Pd}_{80}\text{Si}_{20} \). It is noted that \( f' \) of the order of 10^2 Hz shows good agreement with the measurement frequency \( f \) of the order of 10^2 Hz at where resonant collective motion of many atoms may be excited by means of elastic vibrations.

On the other hand, Lai et al. report that repetition of electropulsing with a peak current density of 10^9 A/m^2 causes the lowering of \( T_x \) by 150–170 K and nanocrystallization of \( \alpha\text{-Fe-Si-B} \) alloys. The effects of electropulsing on crystallization found by them are, qualitatively, very similar to the present results. As already mentioned, however, the
enhancement of crystallization found by Lai et al. may fall in the range which can be found after extrapolation from the enhancement of crystallization observed under a passing dc electric current of $10^7$ A/m$^2$. On the other hand, the crystallization under the present electropulsing appears to be out of this range. Such a different effect found between the electropulsing employed by Lai et al. and the present electropulsing may be associated with the effective frequency of electropulsing. The effective frequency $f'$ of electropulsing employed by Lai et al. is between 5 and 8 kHz, which corresponds to $\tau$ of 0.02–0.03 ms in the present electropulsing after assuming the relationship of $f' = 1/(2\pi\tau)$. The extrapolation of the $i_{d0,c}$ vs $\tau$ data shown in Fig. 15 gives $i_{d0,c} \sim 10^{11}$ A/m$^2$ at $\tau$ of 0.02–0.03 ms, which is two decades larger than the peak current density of $10^9$ A/m$^2$ of electropulsing employed by Lai et al. As mentioned for Figs. 5(a) and 10(a), the decrease in $(\Delta R/R_0)/|\Delta R/R_0|$ attained after electropulsing is as large as $-0.5$ and $-0.6$ for $a$-Cu$_{50}$Ti$_{50}$ and $a$-Pd$_{80}$Si$_{20}$ specimens, respectively, suggesting that both the nucleation and growth processes are enhanced under present electropulsing. In other words, atomic migration intensively proceeds during electropulsing for the order of 1 ms below 420 K in $a$-Cu$_{50}$Ti$_{50}$ and below 350 K in $a$-Pd$_{80}$Si$_{20}$. On the other hand, for the nature of the inhomogeneities existing in a computer-built model amorphous metal, it is reported that the geometrical coordination numbers extend over several atomic distances and the spatial fluctuations of the shear modulus and atomic volume are quite variable. After a shear deformation, the displacement map of atoms shows significant displacements of most atoms in localized regions (the free-volume-rich regions, hereafter) and no displacements in the remaining regions (the free-volume-poor regions, hereafter). We speculate that the present electropulsing excites a collective motion of the free-volume-poor regions as a whole, which brings about migrational motions of most atoms in the free-volume-rich regions. In this case, nucleation and growth are expected to proceed in the free-volume-rich regions. The influence of electric current on the elastic properties found for amorphous alloys suggests that the number of atoms involved in the collective motion of one free-volume-poor region is $10^3$–$10^4$. On the other hand, the number of atoms for one free-volume-poor region in the model amorphous metal, which may not be so different from the value mentioned above after taking in account that the number of atoms for the model calculation is very limited. On the other hand, the excitation of intensive migrational motions of atoms in the free-volume-rich region may correspond to an increase in local temperature in the free-volume-rich region. However, the TTT diagrams shown in Figs. 7 and 14 indicate that no crystallization is expected for $\tau$ ~ 1 ms in $a$-Cu$_{50}$Ti$_{50}$ or for $\tau$ ~ 0.5 ms in $a$-Pd$_{80}$Si$_{20}$, suggesting that a further unknown dynamic process is involved for crystallization under electropulsing.

For $a$-Pd$_{80}$Si$_{20}$, an unknown phase is formed in the early stage of crystallization due to electropulsing and it disappears in the later stage (see Fig. 11). On the other hand, no new phases are observed after crystallization of $a$-Cu$_{50}$Ti$_{50}$ under electropulsing (see Fig. 6). As already mentioned, recent theoretical works for the effects of an electric current on the crystallization in amorphous alloys report that metastable phases can manifest under the influence of an electric current. No observation of new phases after crystallization of $a$-Cu$_{50}$Ti$_{50}$ under electropulsing may reflect that $a$-Cu$_{50}$Ti$_{50}$ always crystallizes to $c$-CuTi, suggesting that the thermodynamic free energy of $c$-CuTi is lower than that of probable metastable crystalline phases under passing electric current in the present current densities. In contrast, various metastable phases have been reported for the crystallization of $a$-Pd$_{80}$Si$_{20}$, suggesting that the difference of the thermodynamic free energy of metastable phases can be modified under an electric current in the present current densities.

For both $a$-Cu$_{50}$Ti$_{50}$ and $a$-Pd$_{80}$Si$_{20}$, crystallization under electropulsing was studied by means of the discharge of a condenser with $\tau$ of 2–0.1 ms. Crystallization proceeds during electropulsing with $i_{d0}$ beyond the threshold $i_{d0,c}$, where $i_{d0,c}$ is a function of $\tau$ and shows a minimum value of 1.4 $10^8$ A/m$^2$ at $\tau$ ~ 2 ms for $a$-Cu$_{50}$Ti$_{50}$ and $2.6 \times 10^9$ A/m$^2$ at $\tau$ ~ 0.9 ms for $a$-Pd$_{80}$Si$_{20}$, respectively. The maximum temperature attained during electropulsing is about 420 K for $a$-Cu$_{50}$Ti$_{50}$ and about 350 K for $a$-Pd$_{80}$Si$_{20}$, respectively, suggesting that the crystallization under electropulsing cannot be explained by thermal activation process alone. One-half of the specimen volume crystallized after a few repetitions of electropulsing with $i_{d0}$ beyond $i_{d0,c}$ for $a$-Cu$_{50}$Ti$_{50}$ and after several repetitions for $a$-Pd$_{80}$Si$_{20}$, indicating that intensive atomic migration proceeded during electropulsing for the order of 1 ms. We surmise that for the density fluctuations existing in amorphous alloys, under electropulsing, a high-density region undergoes resonant collective motion as a whole which induces migrational motions of atoms in the low-density matrix around it. For $a$-Pd$_{80}$Si$_{20}$, the unknown phase is formed in the early stage of the crystallization due to electropulsing and it disappears in the later stage. On the other hand, no new phases are observed after crystallization of $a$-Cu$_{50}$Ti$_{50}$ under electropulsing. These phenomena may be explained by a change in the thermodynamic free energy of phases by an electric current predicted in the recent theoretical works. For $a$-Cu$_{50}$Ti$_{50}$ and $a$-Pd$_{80}$Si$_{20}$, it is also found that for electropulsing with high $i_{d0}$, the electrical resistivity of the specimen decreases at an early stage of the crystallization and increased for further electropulsing. Observations of an unknown phase and the reverse effect at high $i_{d0,c}$ may also be associated with the thermodynamic effects of electropulsing predicted by the theoretical works. We surmise that present electropulsing excites resonant collective motion of...
the free-volume-poor regions which causes migrational atomic motions in the free-volume-rich regions around them. In addition, the thermodynamic effects of an electric current may also be involved for crystallization under the present electropulsing.
