(Received 8 June 1998; published 6 October 1998)

We propose a new nonperturbative method to compute the derivatives of gauge coupling constants with respect to anisotropic lattice spacings (anisotropy coefficients), which are required in an evaluation of thermodynamic quantities from numerical simulations on the lattice. Our method is based on a precise measurement of the finite temperature deconfining transition curve in the lattice coupling parameter space extended to anisotropic lattices by applying the spectral density method. We test the method for the cases of SU(2) and SU(3) gauge theories at the deconfining transition point on lattices with the lattice size in the time direction \( N_t = 4 - 6 \). In both cases, there is a clear discrepancy between our results and perturbative values. A long standing problem, when one uses the perturbative anisotropy coefficients, is a nonvanishing pressure gap at the deconfining transition point in the SU(3) gauge theory. Using our nonperturbative anisotropy coefficients, we find that this problem is completely resolved: we obtain \( \Delta p / T^4 = 0.001(15) \) and \(-0.003(17)\) on \( N_t = 4 \) and 6 lattices, respectively. [S0556-2821(98)05521-0]

I. INTRODUCTION

In order to study the nature of the quark-gluon plasma in heavy ion collisions and in the early Universe, it is important to evaluate the energy density \( \epsilon \) and the pressure \( p \) near the transition temperature of the deconfining phase transition. These quantities are defined by derivatives of the partition function in terms of the temperature \( T \) and the physical volume \( V \) of the system:

\[
\epsilon = -\frac{1}{V} \frac{\partial}{\partial T} \ln Z, \quad p = T \frac{\partial}{\partial V} \ln Z. \tag{1}
\]

The lattice formulation of QCD provides us with a nonperturbative way to compute these quantities by numerical simulations. On a lattice with a size \( N_s^3 \times N_t \), \( V \) and \( T \) are given by \( V = (N_s a_s)^3 \) and \( T = 1/(N_s a_t) \), with \( a_s \) and \( a_t \) the lattice spacings in spatial and temporal directions. Because \( N_s \) and \( N_t \) are discrete parameters, the partial differentiations in Eq. (1) are performed by varying \( a_s \) and \( a_t \), independently on anisotropic lattices.

The anisotropy on a lattice is realized by introducing different coupling parameters in temporal and spatial directions. For an SU\((N_c)\) gauge theory, the standard plaquette action on an anisotropic lattice is given by

\[
S = -\beta_s \sum_{x,i,j \neq 4} P_{ij}(x) - \beta_t \sum_{x,i \neq 4} P_{4i}(x), \tag{2}
\]

where \( P_{\mu\nu}(x) = (1/N_c) \text{Re} \text{Tr} (U_{\mu}(x) U_{\nu}(x + \hat{\mu}) U_{\nu}^\dagger(x + \hat{\nu}) U_{\mu}^\dagger(x)) \) is the plaquette in the \((\mu, \nu)\) plane. With this action, the energy density and pressure are given by [1,2]

\[
\epsilon = -\frac{3N_c^4 T^4}{\xi^3} \left[ \langle a_i \frac{\partial \beta_s}{\partial a_i} - \xi \frac{\partial \beta_s}{\partial \xi} \rangle (\langle P_s \rangle - \langle P_s \rangle_0) \right. \nonumber \]
\[
+ \left. \langle a_i \frac{\partial \beta_s}{\partial a_i} - \xi \frac{\partial \beta_t}{\partial \xi} \rangle (\langle P_t \rangle - \langle P_t \rangle_0) \right], \tag{3}
\]

where \( \langle P_s \rangle \) is the space- (time-)like plaquette expectation value and \( \langle P_s \rangle_0 \) the plaquette expectation value on a zero-temperature lattice. Here, for later convenience, we have chosen \( a_s = \xi \) and \( a_t = a_s / \xi \), as independent variables to vary the lattice spacings, instead of \( a_s \) and \( \xi \) adopted in Ref. [2].

In order to compute \( \epsilon \) and \( p \) from Eqs. (3) and (4) using numerical results from simulations, the values for the derivatives of gauge coupling constants with respect to anisotropic lattice spacings,

\[
\frac{\partial \beta_s}{\partial a_s}, \quad \frac{\partial \beta_t}{\partial a_s}, \quad \frac{\partial \beta_s}{\partial \xi}, \quad \frac{\partial \beta_t}{\partial \xi}, \tag{5}
\]

which we call the anisotropy coefficients, are required. They can be computed from a requirement that, in the scaling region, the effects of anisotropy in the physical observables can be absorbed by a renormalization of the coupling parameters. Similar to the case of the renormalization group beta-function, the anisotropy coefficients do not depend on the temperature, because the renormalization is independent of the temperature.

The calculation of these anisotropy coefficients in the lowest order perturbation theory has been done by Karsch [2]. However, the perturbative coefficients are known to lead to pathological results such as a negative pressure and a nonvanishing pressure gap at the deconfining transition in SU(3) gauge theory. Therefore, nonperturbative values of the anisotropy coefficients are required in order to study the thermodynamic quantities near the phase transition when \( N_t \) is not sufficiently large.

We are interested in the values of the anisotropy coefficients for isotropic lattices (\( \beta_s = \beta_t = \beta \), i.e., \( \xi = 1 \)) where most simulations are performed. In this case, we have

\[
\frac{\partial \beta_s}{\partial a_s} \bigg|_{\xi = 1} = a \frac{d \beta}{da} = 2N_c a \frac{dg}{da}, \tag{5}
\]
where \( a(dg^{-2}/da) \) is the beta function at \( \xi = 1 \), whose nonperturbative values are well studied both in SU(2) and SU(3) gauge theories [3–6]. Furthermore, a combination of the remaining two anisotropy coefficients is known to be related to the beta function [2] by:

\[
\left( \frac{\partial \beta_s}{\partial \xi} + \frac{\partial \beta_t}{\partial \xi} \right)_{\beta_t: \text{fixed}, \xi = 1} = \frac{3}{2} \frac{d \beta}{a}.
\]

Therefore, only one additional input is required to determine the anisotropy coefficients for isotropic lattices.

A nonperturbative determination of the anisotropy coefficients was attempted in Refs. [7–10] using a method that we call “the matching method” in the following. One first determines \( \xi \) as a function of \( \beta_s \) and \( \beta_t \) by matching spacelike and timelike Wilson loops on anisotropic lattices, and then numerically determines \( \partial \gamma / \partial \xi \) at \( \xi = 1 \), where \( \gamma = \sqrt{\beta_s / \beta_t} \).

Interpolation of the Wilson loop data at different sizes or interpolylation of \( \xi \) at different \( \gamma \)'s using an Ansatz is required to evaluate \( \partial \gamma / \partial \xi \) at \( \xi = 1 \).

Alternatively, we can evaluate a nonperturbative value of pressure directly from the Monte Carlo data by “the integral method” [11]. Assuming homogeneity expected when the spatial lattice size is sufficiently large, we obtain the relation \( p = -f \), where \( f = -(T/V) \ln Z \) is the free energy density, which can be evaluated by numerically integrating the plaquette difference \( \langle P_s \rangle + \langle P_t \rangle - 2 \langle P \rangle \) in terms of \( \beta \) on isotropic lattices. The resulting value of the pressure, in turn, provides us with a nonperturbative estimate of an anisotropy coefficient [4,5]. In actual numerical simulations, as the value of \( p \) in the confining phase and near the deconfining transition point is quite small compared with the magnitude of errors, it is difficult to determine the anisotropy coefficients near the transition point [9].

In this paper, we propose a new method to directly compute the anisotropy coefficients at the deconfining transition point. Our method is described in Sec. II. We test the method in the cases of SU(2) gauge theory in Sec. III. The more realistic case of SU(3) gauge theory is studied in Sec. IV. As an application of our nonperturbative anisotropy coefficients, we study the gaps for \( \epsilon \) and \( p \) at the SU(3) deconfining transition for \( N_t = 4 \) and 6. A summary is given in Sec. V.

## II. METHOD

Our method is based on an observation that, in the scaling region, the transition temperature \( T_c = 1/(N_t a_0 (\beta_s, \beta_t)) \) must be independent of the anisotropy of the lattice. Therefore, when we change the coupling constants along the transition curve in the \( (\beta_s, \beta_t) \) plane as \( (\beta_s, \beta_t) \to (\beta_s + d \beta_s, \beta_t + d \beta_t) \) on a lattice with fixed \( N_t \), the lattice spacing in the time direction \( a_t \) does not change:

\[
da_t = \frac{\partial a_t}{\partial \beta_s} d \beta_s + \frac{\partial a_t}{\partial \beta_t} d \beta_t = 0.
\]

We denote the slope of the transition curve at \( \xi = 1 \) by \( r_t \),

\[
r_t = \frac{d \beta_s}{d \beta_t} = -\left( \frac{\partial a_t}{\partial \beta_s} \right)_{\xi = 1} \left/ \frac{\partial a_t}{\partial \beta_t} \right._{\xi = 1} = \left( \frac{\partial \beta_s}{\partial \xi} \right)_{\xi = 1} \left/ \frac{\partial \beta_s}{\partial \xi} \right._{\xi = 1}.
\]

where we used an identity

\[
\left( \frac{\partial \beta_s}{\partial \xi} \right)_{\xi = 1} = \left( \frac{\partial \beta_t}{\partial \xi} \right)_{\xi = 1} = \frac{1}{\beta_s - \beta_t} \left( \frac{\partial \xi}{\partial \beta_s} \right) \left( \frac{\partial \xi}{\partial \beta_t} \right) = \frac{1}{\beta_s - \beta_t} \left( \frac{\partial \xi}{\partial \beta_s} \right) \left( \frac{\partial \xi}{\partial \beta_t} \right). \tag{9}
\]

Hence, the derivatives of \( \beta_s \) and \( \beta_t \) in terms of \( \xi \) are expressed as

\[
\left( \frac{\partial \beta_s}{\partial \xi} \right)_{\xi = 1} = \frac{3r_t}{2(1 + r_t)} \frac{d \beta}{a}.
\]

\[
\left( \frac{\partial \beta_t}{\partial \xi} \right)_{\xi = 1} = \frac{3}{2(1 + r_t)} \frac{d \beta}{a}. \tag{10}
\]

Introducing the conventional notation \( \gamma = \sqrt{\beta_s / \beta_t} \) and \( \beta = \sqrt{\beta_s \beta_t} \), we obtain

\[
\frac{\partial \gamma}{\partial \xi} \left|_{\beta_t: \text{fixed}, \xi = 1} \right. = \frac{3}{4 \beta} \frac{1 - r_t}{1 + r_t} \frac{d \beta}{a}.
\]

Finally, the customarily used forms for the anisotropy coefficients (Karch coefficients) [2] are given by

\[
c_s = \left( \frac{\partial g_s}{\partial \xi} \right)_{\beta_t: \text{fixed}, \xi = 1} = \frac{1}{2 N_c} \left[ \left( \beta + \frac{r_t - 2}{2(1 + r_t)} \frac{d \beta}{a} \right) \right].
\]

\[094505-2\]
where $\beta_1 = 2N_c g_s^{-2} \xi^{-1}$ and $\beta_2 = 2N_c g_s^{-2} \xi$. Therefore, when the value for the beta function is available, we can determine these anisotropy coefficients by measuring $r_i$ from the finite temperature transition curve in the $(\beta_1, \beta_2)$ plane.\(^2\)

In order to determine the transition curve in the coupling parameter space, we compute the rotated Polyakov loop

$$L = \frac{1}{N^3} \sum_{x} \frac{1}{N_c} \prod_{t=1}^{N_t} U_{4}(\vec{x}, t)$$

as a function of $(\beta_1, \beta_2)$, where $z$ is a $Z(N_c)$ phase factor ($z^{N_c} = 1$) such that $\text{arg}(L) \in (-\pi/N_c, \pi/N_c)$. We define the transition point as the peak position of the susceptibility $\chi = N^3(\langle L^2 \rangle - \langle L \rangle^2)$ in $\beta$ for each fixed $\gamma$.

We compute the coupling parameter dependence of $\chi$ in the $(\beta_1, \beta_2)$ plane by applying the spectral density method [13] extended to anisotropic lattices. This enables us to compute the anisotropy coefficients directly from simulations at $\xi \approx 1$ without introducing an interpolation Ansatz. Another good feature of the spectral density method is that the method works well even with data obtained only on isotropic lattices. Therefore, we can use data from previous high statistic simulations performed on isotropic lattices, when the time histories of the Polyakov loop and spacelike and timelike plaquettes are available near the transition point.

Fitting the transition curve with a polynomial

$$\beta_1(\gamma) = \sum_{n=0}^{n_{\text{max}}} f_n(\gamma-1)^n,$$

with $f_n$ the fitting parameters, the slope $r_i$ is given by

$$r_i = \left( \frac{d(\beta_1 / \gamma)}{d(\beta_1 \gamma)} \right)_{\xi=1} \approx \left( \frac{d\beta_1 / d\gamma}{d\beta_1 / d\gamma} \right)_{\xi=1} = f_1,$$

where $(d\beta_1 / d\gamma)_{\xi=1} = f_1$. The range of $\beta_1$ and $\gamma$ in which the spectral density method is reliable is estimated by the condition that the statistical error for the reweighting factor (which is $\langle e^{-\Delta S} \rangle$ when the number of simulation points is 1) is less than 0.5%. We confirm that the results are stable under a variation of $n_{\text{max}}$ when we restrict ourselves to the range discussed above. Choosing a range of $\gamma$ around 1 in such a way that the transition curve is almost straight, we use $n_{\text{max}} = 3$ for the final results.

**III. RESULTS FOR SU(2)**

We first test the method for the case of SU(2) gauge theory at the transition point $\beta_c$ for $N_t = 4$ and 5. Although the method should work well with data only from isotropic lattices, in order to confirm it, we perform Monte Carlo simulations also on several anisotropic lattices for SU(2). On a $16^3 \times 4$ lattice, we perform simulations at $(\beta_1, \beta_2) = (2.300, 2.300), (2.302, 2.302), (2.296, 2.306)$, and $(2.307, 2.298)$. On a $20^3 \times 5$ lattice, we simulate at $(\beta_1, \beta_2) = (2.373, 2.373), (2.375, 2.375), (2.380, 2.370)$, and $(2.368, 2.378)$. At each $(\beta_1, \beta_2)$ on the $N_t = 4$ (5) lattice, we accumulate 500 000 (1 250 000) configurations, each separated by 10 heat-bath sweeps, after thermalization. The statistical errors are estimated using the jackknife method with the bin size of 1000 configurations. We confirm that the errors are stable under a wide variation of the bin size around this value.

Computing the susceptibility in the $(\beta_1, \beta_2)$ plane using data at each simulation point, we check that the results agree well with each other, i.e., the results for the susceptibility from isotropic lattices coincide with the results from anisotropic lattices. For the rest of this section, we combine the results for all four $(\beta_1, \beta_2)$ combinations to compute the susceptibility with the spectral density method. In Fig. 1, we plot the susceptibility for $N_t = 4$ at $\gamma = 0.995, 1.000$, and 1.005. The results for the peak position $\beta_1$ of the susceptibility computed at various values of $\gamma$ are summarized in Fig. 2 for $N_t = 4$ and 5.

Fitting the results for the transition curve, we obtain the values for $\beta_1$ and $r_i$ at $\xi = 1$, as summarized in Table I. Combining the values of $r_i$ with a result of the SU(2) beta function [4] at $\beta_c(\xi = 1)$, we obtain the anisotropy coefficients (11) and (12). The results are summarized in Table II. Because no errors for the beta function are given in Ref. [4], we disregard their contribution to the errors of the anisotropy coefficients.

In Fig. 3, we compare our results for the Karsch coefficients with the results of the perturbation theory (dot-dashed curves) [2] and the integral method (dotted curves) [4]. We find significant discrepancies between our results and the results of the perturbation theory. On the other hand, our results are consistent with the results from the integral method.
Let us now study the more realistic case of the SU~3 gauge theory. We analyze the high statistic data for the SU~3 gauge theory obtained by the QCDPAX Collaboration. Simulations were performed at the deconfining transition point for N_t = 4 and 6. For N_t = 4, the lattice sizes are 24^2 \times 36^2 \times 4^2 and 24^3 \times 4, with 712,000 and 910,000 pseudo-heat-bath iterations, respectively. For N_t = 6, data on 36^2 \times 48^2 \times 4, 24^3 \times 6, and 20^3 \times 6 lattices with 1,112,000, 480,000, and 376,000 iterations are available. The Polyakov loop and the plaquettes are measured every iteration. Details of the simulation parameters are given in Ref. For the bin size in the jack-knife analysis, we adopt the same values as in Ref.

### IV. RESULTS FOR SU(3)

Let us now study the more realistic case of the SU(3) gauge theory. We analyze the high statistic data for the SU(3) gauge theory obtained by the QCDPAX Collaboration. Simulations were performed at the deconfining transition point for N_t = 4 and 6. For N_t = 4, the lattice sizes are 24^2 \times 36^2 \times 4^2 and 12^3 \times 24 \times 4, with 712,000 and 910,000 pseudo-heat-bath iterations, respectively. For N_t = 6, data on 36^2 \times 48^2 \times 4, 24^3 \times 6, and 20^3 \times 6 lattices with 1,112,000, 480,000, and 376,000 iterations are available. The Polyakov loop and the plaquettes are measured every iteration. Details of the simulation parameters are given in Ref. For the bin size in the jack-knife analysis, we adopt the same values as in Ref.

#### A. Anisotropy coefficients

The results for the susceptibility on the largest spatial lattices are given in Figs. 4 and 5. Because the transition is of first order for SU(3), the peak of the susceptibility is quite clear when the spatial lattice size is large enough, as shown in Figs. 4 and 5. Note the difference in the vertical scales between Figs. 1 and 4.

### FIG. 2. Polyakov loop susceptibility in the SU(2) gauge theory as a function of (βs, βt) obtained on (a) 16^3 \times 4 and (b) 20^3 \times 5 lattices. Simulation points are shown by filled circles. The bold lines represent the peak position of the susceptibility and the dashed lines their errors. The magnitude of the susceptibility is shown by tone for the range (a) 8.2<χ<10.4 and (b) 9.0<χ<11.2, respectively, where different tone corresponds to a difference Δχ=0.2.

### FIG. 3. Anisotropy coefficients c_s and c_t for the SU(2) gauge theory. Our nonperturbative results are given by filled circles. The dot-dashed curves are the results of the perturbation theory [2]. The dotted curves are the results from the integral method [4]. No errors are published for these curves.
Our results for the slope $r_t$ are summarized in Table III. Except for the case of the $24^3 \times 6$ lattice where the simulation point is slightly off the transition point, the errors become larger with decreasing spatial volume, because the peak of the susceptibility becomes less clear on small lattices. From Table III, we find that the slopes at $N_t = 4$ with different spatial lattice volumes completely agree with each other. As shown in Figs. 4 and 5, the peak of the susceptibility for $N_t = 6$ is less sharp compared with that for $N_t = 4$ with the same relative spatial volume $(N_s/N_t)^3$ due to the fact that the transition is weaker for $N_t = 6$ [14]. Therefore, with comparable statistics, $r_t$ has a larger statistical error for $N_t = 6$. Unlike in the case of $N_t = 4$, the central values for the slope for $N_t = 6$ given in Table III vary with the spatial volume by about one standard deviation. However, because the volume dependence is not uniform, we consider that it is caused by statistical fluctuations. We use the values obtained on the largest spatial lattices for our final results.

Our results for the anisotropy coefficients are summarized in Table IV. For our final results, we adopt the beta function computed from a recent string tension data by the SCRI group [6]. See a subsection below for a discussion about the influence on the results from the choice of the beta function.

B. Pressure gap and latent heat

As an application of our nonperturbative anisotropy coefficients, we reanalyze the thermodynamic quantities $\epsilon$ and $p$...
At a first order transition point, we have a finite gap for the deconfining transition point using the plaquette data by the SCRI group [14]. In terms of the slope $r_i$ and the beta function, the conventional combinations $\epsilon - 3p$ and $\epsilon + p$ are given by

$$\frac{(\epsilon - 3p)}{T^4} = -3N_t a \frac{d\beta}{d\alpha}\{\langle P_+\rangle + \langle P_\pm\rangle - 2\langle P_0\rangle\}, \quad (16)$$

$$\frac{(\epsilon + p)}{T^4} = 3N_t a \frac{d\beta}{d\alpha}\frac{r_i - 1}{r_i + 1}\{\langle P_+\rangle - \langle P_\pm\rangle\}. \quad (17)$$

At a first order transition point, we have a finite gap for energy density, the latent heat, but expect no gap for pressure. It is known that the perturbative anisotropy coefficients have a difficulty which leads to a nonvanishing pressure gap at the deconfining transition point: $\Delta p/T^4 = \frac{32}{3}(3)$ and $-0.14(2)$ at $N_t = 4$ and 6 [14].

New values for the gaps in $\epsilon$ and $p$ using our nonperturbative anisotropy coefficients are summarized in Table V. For the pressure gap, we obtain

$$\Delta p/T^4 = \begin{cases} 
0.001(15) & \text{for } N_t = 4, \\
-0.003(17) & \text{for } N_t = 6. 
\end{cases} \quad (18)$$

We find that the problem of nonzero pressure gap is completely resolved with our nonperturbative anisotropy coefficients.

### C. Choice of the beta function

In Table IV, we study the influence of the choice of the beta function on the anisotropy coefficients. We compare (i) the beta function computed from a recent string tension data by the SCRI group [6], (ii) that from a Monte Carlo renormalization group (MCRG) study by the QCDTARO Collaboration [3], and (iii) that from a study of $\beta_c(N_t)$ by the Bielefeld group [5]. The SCRI beta function is computed using a fit of the string tension for 5.6 $\leq \beta \leq 6.5$. We note that the QCDTARO beta function is based on a fit of mean-field improved gauge coupling constant using the results of plaquette at $\beta > 5.8$; i.e., $\beta_c(N_t = 4) \approx 5.69$ is slightly off the range of validity [3,15]. Also the beta function by the Bielefeld group seems to be problematic around $\beta_c(N_t = 4)$, because it is largely affected by the data of $\beta_c(N_t = 3)$ where we cannot expect universal scaling. Accordingly, the beta-function of the Bielefeld group shows a systematic deviation from the data of a MCRG study at $\beta \leq 6$ [5].
TABLE V. Gaps for thermodynamic quantities in the SU(3) gauge theory at the deconfining transition point using our non-perturbative anisotropy coefficients. Plaquette data are taken from Ref. [14]. The low-temperature hadronic phase and the high-temperature quark-gluon-plasma phase are separated as described in Ref. [14]. We reanalyze \((e-3p)/T^4\) also, using the SCRI beta function.

These beta functions are plotted in Fig. 6. At \(\beta_c(N_t=6)\), different beta functions coincide with each other within 5%, while, at \(\beta_c(N_t=4)\), they vary by about 20%. Because only the SCRI beta function is reliable at \(\beta_c(N_t=4)\) as discussed in the previous paragraph, we adopt the SCRI beta function for our final results.

In order to compare the anisotropy coefficients from different references, however, it is important to check the effect of the beta-function on the results. From Table IV, we see that the results for the anisotropy coefficients using different beta-functions agree well with each other at \(N_t=6\). At \(N_t=4\), however, the anisotropy coefficients depend very much on the choice of the beta function. Accordingly, we find that the results for the latent heat are consistent with each other at \(N_t=6\): \(\Delta e/T^4=1.569(40)\), 1.539(39), and 1.515(38) with SCRI, QCDTARO, and Bielefeld beta functions, respectively. At \(N_t=4\), we find a sizable dependence on the choice of the beta function: \(\Delta e/T^4=2.074(34)\), 1.877(30), and 2.265(37) using SCRI, QCDTARO, and Bielefeld beta functions. For the pressure gap, on the other hand, because the beta function appears only as a common overall factor in Eqs. (16) and (17), the conclusion that \(\Delta p\) vanishes with our anisotropy coefficients does not depend on the choice of the beta function.

![FIG. 6. Nonperturbative beta functions in the SU(3) gauge theory.](image6.png)

![FIG. 7. Anisotropy coefficients in the SU(3) gauge theory. Our nonperturbative results are given by filled circles. The dot-dashed curves are the results of the perturbation theory [2]. The open squares are those from a matching of Wilson loops [9]. Open triangles and thin lines are the results of a matching method [10] combined with the SCRI beta function [6]. The dotted curves are the results from the integral method [5]. No errors are published for the results from the integral method.](image7.png)

D. Comparison with other methods

In Fig. 7, we summarize our results for the Karsch coefficients together with previous values; the perturbative results [2], results from the integral method [5], and those from the matching of Wilson loops on anisotropic lattices [9,10]. No errors are published for the results from the integral method. We find that all nonperturbative methods give values which deviate from the results in the perturbation theory.

Comparing the results from different nonperturbative methods, we find that, although the deviations from the perturbation theory are roughly consistent with each other, the central values are different by more than three standard deviations, when we take the published errors.

We think that one origin of the variation among different methods at \(\beta_c(N_t=4)\) is the beta function. Note that the results from Refs. [9] (matching method) and [5] (integral method) are computed using the beta function of the Bielefeld group, while our results and the results from Ref. [10] (matching method) are using the SCRI beta function. From Table IV, we note that, if we adopt the beta-function of the Bielefeld group, our results are consistent with those of Ref. [9] at \(\beta_c(N_t=4)\).

At \(\beta_c(N_t=6)\), on the other hand, the difference in the results is not due to the beta function, because the systematic error due to the choice of the beta function is small as discussed in the previous subsection. In order to see this, we study \(\partial g/\partial z\), which can be computed without using the beta function in the matching method. The values of \(\partial g/\partial z\) ob-
tained in Ref. [10] are reported to be consistent with those from the integral method [5], but are different to another result from the matching method [9]. Performing a quadratic interpolation in $\beta$, we find $\delta \gamma/\delta \xi = 0.64(1)$ [10], 0.66(2) [5], and 0.74(2) [9] at $\beta_c(N_t = 6)$. Our result 0.707(10) given in Table IV is around the center of these values. A careful study of systematic errors in each method is required to understand the variation between different methods.

V. CONCLUSIONS

We have computed the anisotropy coefficients for the SU(2) and SU(3) gauge theories by measuring the transition curve of the deconfining transition in the $(\beta_s, \beta_t)$ plane. One of the essential ingredients of our approach is the application of the spectral density method, which enables us to determine the anisotropy coefficients directly from simulations at $\xi = 1$. We note that the spectral density method is useful to avoid interpolation Ansätze also in the matching method.

Our nonperturbative results for the anisotropy coefficients are summarized in Tables II and IV. Our results shown in Fig. 7 suggest that the Karsch coefficients converge to the perturbative values slightly faster than that suggested by the central values from Refs. [5] and [10]. Applying the results for SU(3), we reanalyzed the thermodynamic quantities at the deconfining transition point on $N_t = 4$ and 6 lattices. We obtain vanishing pressure gaps with our nonperturbative anisotropy coefficients, thereby solving a long standing problem of nonzero pressure gap with the perturbative coefficients.

ACKNOWLEDGMENTS

We are grateful to O. Miyamura, A. Nakamura and H. Matsufuru for useful discussions and sending us the data for the QCDTARO beta function. We also thank A. Ukawa, T. Yoshié, Y. Aoki, T. Kaneko, R. Burkhalter, and H. P. Shanahan for helpful suggestions and comments.
