We show that the low frequency microwave absorption of an ensemble of small metallic grains at low temperatures is dominated by a mesoscopic relaxation mechanism. Giant positive magnetoresistance and very strong temperature dependence of the microwave conductivity is predicted.

Suggested PACS index category: 05.20-y, 82.20-w

Microwave absorption in an ensemble of metallic grains has been investigated both theoretically and experimentally in many papers. (See for Refs. [1–4].) At high temperatures quantum effects can be neglected and the effective microwave conductivity at frequency  $\omega$  is given by the classical Debye formula,

$$\sigma_D = \frac{\omega^2}{\sigma_{cl}}. \quad (1)$$

Here  $\sigma_{cl}$  is the classical Drude conductivity determined by elastic scattering. At low temperatures the quantum nature of electronic states in grains becomes essential and statistics of the electron levels determines the microwave absorption [1–4]. However all quantum effects considered so far result in the microwave conductivity of the order or smaller than  $\sigma_D$ . In this Letter we discuss the mechanism of microwave absorption which can be much stronger than the classical one given by Eq. (1).

At sufficiently high radiation frequency  $\omega$  the absorption is dominated by the resonant mechanism, i.e., by the direct transitions between electron levels [1,2], and the microwave conductivity is determined by the probability density  $P(s)$  of energy spacing  $s$  between adjacent levels. This quantity is usually described by the Wigner-Dyson distribution. At  $s \ll \Delta$ , where  $\Delta$  is the mean level spacing, the probability density behaves as [5] (see the insert on Fig. 1)

$$P(s) = C_\beta s^\beta / \Delta^{\beta+1}. \quad (2)$$

The exponent  $\beta$  is determined by the global symmetry of the system. For the orthogonal ensemble  $\beta = 1$  and  $C_\beta = \pi^2/6$ . In the unitary case,  $\beta = 2$  and  $C_\beta = \pi^2/3$ . Finally, the symplectic ensemble is characterized by  $\beta = 4$  and  $C_\beta = 16\pi^2/135$ .

It is well known, however, that absorption of radiation in two level systems is determined at low  $\omega$  by the relaxation mechanism. Mandelstam and Leontovich proposed this mechanism for sound attenuation in gases with slow internal degrees of freedom [6]. For microwave absorption in doped semiconductors relaxation absorption was suggested by Pollack and Geballe [7].

The contribution of this mechanism to the microwave conductivity of metallic grains  $\sigma_R$  depends strongly on

the relation between  $\Delta$  and the level broadening  $\Gamma$ . For  $\Gamma \gg \Delta$ , the relaxation mechanism of absorption in granular metals was shown in Ref. [8] to determine under certain conditions both the microwave conductivity and the magnetoconductance of metallic grains. Here we consider the opposite limit  $\Gamma \ll \Delta$  when the energy levels are well resolved. It turns out that the microwave absorption  $\sigma_R$  as well as the magnetoconductance are giant in this limit, i.e.,  $\sigma_R$  exceeds both Eq. (1) and results of Ref. [8] by several orders of magnitude.

We now discuss the physical picture of the relaxation absorption of applied electric field of frequency  $\omega$ . In adiabatic approximation temporal energy levels  $\epsilon_i(t)$  oscillates with the same frequency. Since the populations of the energy levels follows adiabatically the motion of the levels themselves, the electron distribution becomes nonequilibrium without any interlevel electron transitions. Relaxation of the nonequilibrium distribution due to inelastic processes leads to the entropy production and therefore to the absorption of the energy of the external field.

To simplify the situation, we will restrict ourselves to the low temperature case when  $T \ll \Delta$ . (Later we will also discuss the situation at  $\Gamma \ll \Delta < T$  qualitatively.) We will see that at  $\omega \ll T$  the relaxation mechanism of absorption is determined by rare grains where the first excited level is separated from the ground state by small energy  $s \ll T$ . This implies that the ground and the first excited states in the grains form two level systems which are effectively isolated from the rest of the spectrum.

The population  $N(t)$  of the first excited state with the energy  $s(t)$  is governed by the equation

$$\frac{dN(t)}{dt} = -\frac{N(t) - N_0(s(t))}{\tau_\epsilon}. \quad (3)$$

Here  $N_0(s(t)) = (1 + \exp(s(t)/T))^{-1}$  is the adiabatic equilibrium population of the first excited level and  $\tau_\epsilon$  is the relaxation time of the level due to the electron-phonon interaction. Eq. (3) is applicable provided  $s \gg \Gamma$ .

It is crucial for our discussion that the relaxation rate for a two level system vanishes with  $s$ . For a two level system embedded into 3D insulating environment with phonons,  $\tau_\epsilon \sim s^{-4}$  for  $s \rightarrow 0$ . The fact that  $\tau_\epsilon(s)$  diverges

so rapidly for small  $s$  leads, as we will see, to divergences in  $\sigma_R$ . To provide the proper cutoff we need to include the contribution to  $\tau_\epsilon^{-1}$  from the processes that involve the second excited state. The latter is typically separated in energy by  $\Delta \gg T$  and we get a finite, though exponentially small, relaxation rate at  $s = 0$ :

$$\frac{1}{\tau_\epsilon(s)} = \frac{1}{\tau_0} \left(\frac{s}{\Delta}\right)^4 + \frac{1}{\tau_m}, \quad (4)$$

where

$$\frac{1}{\tau_0} \sim \frac{\Delta^5 L^2 l T}{\Omega_D^2 v_s^3}; \quad \frac{1}{\tau_m} = \frac{\Delta}{T \tau_0} \exp\left(-\frac{\Delta}{T}\right), \quad (5)$$

$\Omega_D$  is the Debye frequency in the metal,  $v_s$  denotes the velocity of sound,  $L$  is the size of the sample and  $l$  is the elastic mean free path. To interpret Eq. (5) we present the first term in Eq. (5) in the form  $(s^3/\Omega_D^2)(\Delta/s)(kl)(kl)^2(T/s)$ , where  $k = (s/\hbar v_s)$  is the wave number of a phonon with the energy  $s$ . The first factor here corresponds to the conventional expression for the relaxation rate in clean bulk metal at  $\epsilon_i \approx T$ . We are considering a transition between two particular levels without summing over the final states (as is usual in the bulk case); this gives rise to the second factor. In the dirty case ( $kl < 1$ ) the electron phonon relaxation time is known to be suppressed [9] (third factor). If the phonon wave length exceeds the system size  $L$  as well, the electron-phonon coupling in the dipole approximation is reduced, and the fourth factor appears. Finally at  $s < T$  the large population number of phonons leads to the last factor.

To evaluate  $\sigma_R$  we consider the power  $Q$  absorbed in a grain. Given the amplitude of the microwave electric field  $E$  and the volume of the grain  $V$ ,

$$Q = \omega \int dt \frac{ds}{dt} N(t); \quad \sigma_R = \frac{Q}{E^2 V}. \quad (6)$$

In the ohmic approximation we obtain the Debye-type expression for the averaged microwave conductivity,

$$\sigma_R = \langle \left(\frac{ds}{dE}\right)^2 \rangle \frac{1}{V} \int ds P(s) \frac{dN_0}{ds} \frac{\omega^2 \tau_\epsilon(s)}{1 + (\omega \tau_\epsilon(s))^2}. \quad (7)$$

Here  $\langle \dots \rangle$  stands for the averaging over the random scattering potential. The random matrix elements were assumed to be statistically independent from the spectrum. This assumption can be verified by a straightforward calculation. We will present this calculation elsewhere.

The distribution  $P(s)$  of the nearest neighbor spacing  $s$  is known to be determined by the global (spin and/or time reversal) symmetry of the system.  $\sigma_R$ , because of its dependence on  $P(s)$  as seen in Eq. (7), should be very sensitive to weak magnetic field  $H$  and to spin-orbit scattering rate  $1/\tau_{so}$ . Here we restrict ourselves only to the three asymptotic regimes: (i) orthogonal, when  $H = 0$

and  $\tau_{so} = \infty$ , (ii) unitary, when the magnetic field is strong and (iii) symplectic ( $H = 0$ , while  $\tau_{so}$  is short.) We also discuss the particularly interesting case of the combination of strong spin-orbit scattering and a weak magnetic field. With this exception we do not present here explicit formulae for the absorption in the crossover regimes. Here we will consider only linear absorption.

Substitution of Eq. (5) into Eq. (7) gives

$$\sigma_R = \frac{\omega^2 \tau_0}{4VT} \langle \left(\frac{ds}{dE}\right)^2 \rangle \phi\left(\frac{\Delta}{2T}, \omega \tau_m, \frac{\tau_0}{\tau_m}\right), \quad (8)$$

where

$$\phi(a, b, c) = \int_0^\infty \frac{(x^4 + c)x^\beta dx}{(x^4 + c)^2 + (bc)^2} \frac{1}{\cosh^2(ax)}. \quad (9)$$

For orthogonal ( $\beta=1$ ) and unitary ( $\beta=2$ ) ensembles of metallic grains ( $\tau_{so} s^* \ll 1$ ) the typical value of  $s$  determining the integral contribution in Eq. (7) is

$$s \sim s^* = \Delta (\max[\omega \tau_0, \tau_0/\tau_m])^{1/4}, \quad (10)$$

provided  $s^* \ll T, \Delta$ . In this limit,  $\sigma_R$  is

$$\sigma_R = \frac{\pi \omega^2 \tau_0}{16VT} \langle \left(\frac{ds}{dE}\right)^2 \rangle \left(\frac{\tau_m}{\tau_0}\right)^{1/2\beta} f_\beta(\arctan(\omega \tau_m)) \quad (11)$$

with

$$f_\beta(k) = \operatorname{cosec}\left(\frac{\pi}{2\beta}\right) (\cos k)^{1/2\beta} \cos\left(\frac{k}{2\beta}\right). \quad (12)$$

The amplitude of electric field decays over Thomas-Fermi screening length  $r_0 = \sqrt{D/4\pi\sigma_{cl}} \ll L$  from its vacuum value  $E$  down to  $E\omega/\sigma_{cl} \ll E$ . (Here  $D$  is the diffusion constant of electrons.) This small electric field in the bulk gives the main contribution to the classical Debye formula Eq. (1). On the contrary, the sensitivity Eq. (12) is determined by the small region of the width of order of  $r_0$  near the surface, where the value of the electric field is of the order of  $E$ . A calculation analogous to that in Ref. [8] gives

$$\langle \left(\frac{ds}{dE}\right)^2 \rangle \sim \frac{e^4 r_0^4}{\beta \sigma_{cl} V}. \quad (13)$$

As a result, in the orthogonal case

$$\sigma_R^o = C\alpha\sigma_D \times \begin{cases} \left(\frac{T}{\Delta}\right)^{1/2} \exp\left(\frac{\Delta}{2T}\right) & \omega\tau_m \ll 1 \\ \frac{1}{\sqrt{2}} \left(\frac{1}{\omega\tau_0}\right)^{1/2} & \omega\tau_m \gg 1 \end{cases}, \quad (14)$$

while for the unitary ensemble,

$$\sigma_R^u = C\alpha\sigma_D \times \begin{cases} \left(\frac{4T}{\Delta}\right)^{1/4} \exp\left(\frac{\Delta}{4T}\right) & \omega\tau_m \ll 1 \\ 2 \cos\left(\frac{\pi}{8}\right) \left(\frac{1}{\omega\tau_0}\right)^{1/4} & \omega\tau_m \gg 1 \end{cases}, \quad (15)$$

where

$$\alpha = \pi \Delta^2 \tau_0 / 372T \quad (16)$$

and  $C$  is a constant of order unity which depends on the geometry of the grain and on the direction of the electric field. If the grain is cubic and the microwave field is perpendicular to its face, then  $C = 1$ . Therefore in both the orthogonal and unitary cases  $\sigma_R$  is much larger than the classical Debye conductivity Eq. (1).

In the absence of electron-electron Coulomb interaction, a similar approach is applicable even at  $T > \Delta > \Gamma$  when many well resolved levels participate the absorption. In this case  $\sigma_R \sim \alpha' \sigma_D$  and  $\alpha' = e^2 r_0^2 V^{-1} \tau_\epsilon(T)$ . This matches the results [8] at  $\Delta \sim \Gamma$ .

As usual, one can drive an orthogonal system into a unitary one by applying magnetic field  $H$ . This leads to a giant negative magnetoconductance. Here we consider it only qualitatively and only at  $\omega \tau_M \ll 1$ . The field needed to reduce from  $\sigma_R^o$  to  $\sigma_R^u$  is

$$H \sim H(s^*) = \left(\frac{s^*}{\Delta}\right)^{\frac{1}{2}} H_0, \quad (17)$$

where given the cross-section of the grain  $A$  and its dimensionless (in units  $e^2/\hbar$ ) conductance  $g$ , the characteristic field  $H_0$  is

$$H_0 = \frac{\hbar c}{eAg^{\frac{1}{2}}} \quad (18)$$

The field  $H(s^*)$  reduces  $\sigma_R$  dramatically from  $\sigma_R^o$  to  $\sigma_R^u$ .

Now let the spin-orbit scattering rate  $\tau_{so}^{-1}$  exceed  $\Delta$ . In this symplectic case  $P(s) \sim s^4/\Delta^5$  and the integral over  $s$  in Eq. (6) is determined by  $s \sim T$ . At low  $\omega \ll \tau_\epsilon^{-1}$  (which means  $s^* \ll T$ ) we have

$$\sigma_R^s = C \frac{64\pi^2}{45} \sigma_D \alpha \frac{T}{\Delta}; \quad \text{if } \omega \ll (T/\Delta)^4 \tau_0^{-1}. \quad (19)$$

At small frequencies  $\sigma_R^s$  turns out to be temperature independent and larger than  $\sigma_D$  by the factor  $\alpha T/\Delta \sim \tau_0 \Delta \gg 1$ . At high frequencies the condition  $s^* \ll T$  is violated. In the interval  $T < s^* < \Delta$  (or  $(T/\Delta)^4 < \omega \tau_0 < 1$ )  $\sigma_R$  is  $\omega$ -independent for all ensembles and

$$\sigma_R^{o,u,s} = \frac{CC_\beta}{16\pi\beta(\beta+5)} (T/\Delta)^{\beta+3} \frac{t_M}{\tau_0} T \quad (20)$$

In a symplectic grain each energy level is double degenerated due to the T-invariance. An applied magnetic field splits this Kramers doublet and therefore increases  $P(s)$  at small  $s$ . According to Kravtsov and Zirnbauer [10]

$$P(s, H) - P(s, 0) \sim \frac{s^2}{s(H)^3} \exp\left[-\frac{s^2}{s(H)^2}\right] \quad (21)$$

Therefore the distribution function has a peak at

$$s = s(H) \equiv \Delta \frac{H}{H_0} \quad (22)$$

and  $P(s) \sim s^2$  below this peak. Calculation of the sensitivity  $\langle (ds/dE)^2 \rangle$  and  $\tau_\epsilon$  for a split Kramers doublet

require some caution: without magnetic field both the external electric field and lattice deformation are unable to split a doublet (for example  $ds/dE = 0$  for  $H = 0$ ). Therefore at  $H < H_0$

$$\langle \left(\frac{ds}{dE}\right)^2 \rangle \sim e^2 r_0^2 \frac{\Delta}{4\pi\sigma_{cl}} \left(\frac{H}{H_0}\right)^2, \quad (23)$$

$$\frac{1}{\tau_\epsilon} \sim \frac{1}{\tau_0} \left(\frac{s}{\Delta}\right)^4 \left(\frac{H}{H_0}\right)^2 + \frac{1}{\tau_m}. \quad (24)$$

Substituting Eq. (21) into Eq. (7) we get the expression for grain magnetoconductance in the limit  $\omega \tau_\epsilon \ll 1$  in the presence of substantial spin-orbit scattering. For  $s(H) > s^*$ , i.e.,  $H^4/H_0^4 > \omega \tau_0, \tau_0/\tau_m$ , we get

$$\sigma_R(H) - \sigma_R(0) \sim \left(\frac{H_0}{H}\right)^3 \sigma_R^u \gg \sigma^s(H=0). \quad (25)$$

Thus we have a giant positive magnetoconductance that increases rapidly with the decreasing magnetic field until  $H > H_0 s^*/\Delta$ . Therefore at  $H \sim H_0 s^*/\Delta$ , the magnetoconductance has a sharp maximum. The magnetic field dependence of  $\sigma_R$  both for  $\tau_{so} \rightarrow \infty$  and for short  $\tau_{so}$  is qualitatively illustrated in Fig. 1.

Let us now estimate  $\sigma_R$ . Consider a metallic grain with  $\Delta \sim 1K$  (the size is about  $L \sim 150\text{\AA}$ ).  $\tau_0$  can be estimated as  $\tau_0 \sim 10^{-7}$  sec. Then we get  $\alpha \sim 10^2$  at  $T \sim 0.3K$ . Therefore, at  $\omega \sim 10^5 \text{Hz}$  we predict  $\sigma_R$  in the orthogonal case to be about three orders of magnitude larger than  $\sigma_D$ . Under these conditions  $s^* \sim 0.3K$  and  $H_0 \sim 10T$  (at  $g \sim 10$ ), i.e.,  $H \sim 3T$  will make the absorption several times smaller.

Note that the magnetoconductance is negative and positive in the orthogonal and symplectic cases respectively, i.e., the sign of the magnetoconductance is opposite to usual weak localization [11,12]. This is natural since classical microwave conductivity Eq. (1) is inversely proportional to  $\sigma_{cl}$ .

So far we have neglected effects of the Coulomb interaction between electrons. First of all, our consideration was based on the Wigner-Dyson distribution  $P(s)$ . Its applicability in the presence of interactions is not as clear as in their absence. Experimental study of the microwave absorption could provide information on this probability distribution.

Another Coulomb effect to consider is the contribution of the electron-electron interaction to the level broadening  $\Gamma$ . We argue that in the limit  $T \ll \Delta$  this contribution does not exist and  $\Gamma$  is determined entirely by the phonon scattering  $\Gamma = \tau_\epsilon^{-1}$ . Coulomb interactions can only renormalize the one-electron energy of the first excited state but not to broaden it, because the inelastic transitions due to electron-electron interaction are forbidden by the energy conservation law. Therefore Eq. (7) remains valid even for strongly correlated electrons.

As it has been mentioned above, without Coulomb interaction there is a big interval  $\Gamma \sim \tau_\epsilon^{-1} < \Delta < T$  where

our two level approximation is not valid and many levels in each grain contribute to the absorption. These levels are still well resolved. On the other hand the electron-electron interaction is known to dominate  $\Gamma$  at high temperatures:  $\Gamma_{ee} \geq \Delta$  for  $T > \Delta$  [12]. This makes calculations for  $\Delta < T < \Delta(\tau_o\Delta)^{1/5}$  anything but trivial. Indeed, calculated in Ref. [12]  $\Gamma_{ee}$  is the broadening of one-particle states. The exact many-electron states can be broadened only by phonons. However, the spacing between these exact states  $\Delta_{ex}(\epsilon)$  is of the order of  $\Delta$  only for several low energy excitations. With increasing the energy  $\epsilon$  the spacing  $\Delta_{ex}(\epsilon)$  decreases very quickly. We find it possible that the results of [8] are valid until  $T > T^*$  where  $T^*$  is determined by the relation  $\Delta_{ex}(T^*) = \Gamma_{ph}(T^*)$ . If so, the matching should take place in the interval  $\Delta < T < T^*$ . We have to admit that much better understanding of the relation between exact states and quasiparticles and of electron-phonon interaction in the closed system is needed in order to develop a theory of microwave absorption at  $\Delta < T < \Delta(\tau_o\Delta)^{1/5}$ .

In addition to the absorption of the electric field, one can consider the effect of an a.c. magnetic field. Here we only mention results of Ref. [13]. The authors of these papers assumed that the broadening of the energy levels is energy independent and found that the energy dissipation in the time dependent magnetic field can be much larger than the classical one at  $\Delta \gg \Gamma$ . The sign of the magnetoresistance in this case turns out to be the same as we found here, i.e., magnetoresistance is positive in an orthogonal ensemble and negative in a symplectic one. We believe, however, that the energy dependence of  $\Gamma$  is crucial for this problem as well, and we plan to present a quantitative theory elsewhere.
