ABSTRACT

We present a novel radiation hydrodynamics code, START, which is a smoothed particle hydrodynamics (SPH) scheme coupled with accelerated radiative transfer. The basic idea for the acceleration of radiative transfer is parallel to the tree algorithm that is hitherto used to speed up the gravitational force calculation in an N-body system. It is demonstrated that the radiative transfer calculations can be dramatically accelerated, where the computational time is scaled as $N_p \log N_s$ for N_p SPH particles and N_s radiation sources. Such acceleration allows us to readily include not only numerous sources but also scattering photons, even if the total number of radiation sources is comparable to that of SPH particles. Here, a test simulation is presented for a multiple source problem, where the results with START are compared to those with a radiation SPH code without tree-based acceleration. We find that the results agree well with each other if we set the tolerance parameter as $\theta_{crit} \leq 1.0$, and then it demonstrates that START can solve radiative transfer faster without reducing the accuracy. One of the important applications with START is to solve the transfer of diffuse ionizing photons, where each SPH particle is regarded as an emitter. To illustrate the competence of START, we simulate the shadowing effect by dense clumps around an ionizing source. As a result, it is found that the erosion of shadows by diffuse recombination photons can be solved. Such an effect is of great significance to reveal the cosmic reionization process.

Key words: hydrodynamics – radiative transfer – methods: numerical – diffuse radiation.

1 INTRODUCTION

The radiative transfer (RT) in 3D space is virtually a 6D problem for a photon distribution function in the phase space. So far, various RT schemes have been proposed, some of which are coupled with hydrodynamics (Iliev et al. 2006, 2009). In a grid-based scheme, the RT can be reduced to a 5D problem without the significant reduction of accuracy [e.g. the authentic RT (ART) scheme that is proposed in Nakamoto, Umemura & Susa (2001) and Iliev et al. (2006)]. In a smoothed particle hydrodynamics (SPH) scheme, if diffuse scattering photons are neglected, the computational cost is proportional to $N_p N_s$, where N_p and N_s are the number of SPH particles and that of radiation sources, respectively. This type of radiation transfer solver can be coupled with the hydrodynamics (e.g. Susa 2006; Iliev et al. 2006, 2009).

But, in various astrophysical problems, diffuse scattering photons play a significant role, for example, in photoionization of a highly clumpy medium. The treatment of diffuse radiation is a hard

barrier owing to its high computational cost. Susa (2006) proposed Radiation-SPH (RSPH) scheme, in which the radiation transfer based on ray-tracing is coupled with SPH. Since SPH particles are directly used to integrate optical depths, high-density regions can be automatically resolved with high accuracy. The code can actually treat multiple radiation sources, but the computational cost increases in proportion to the number of radiation sources. Hence, it is difficult to include numerous radiation sources. For the same reason, recombination photons are hard to involve, since each SPH particle should be treated as a radiation source. Thus, in the applications of RSPH, the on-the-spot approximation is assumed (Spitzer 1978), where recombination photons are supposed to be absorbed on the spot, and therefore transfer of diffuse radiation is not solved. The RSPH has been applied to explore the radiative feedback on first generation object formation (Susa & Umemura 2004, 2006; Susa 2007, 2008; Hasegawa, Umemura & Susa 2009b; Susa, Umemura & Hasegawa 2009), where ionization of hydrogen and photodissociation of hydrogen molecules H_2 by ultraviolet (UV) radiation are key physics. But, diffuse radiation potentially changes the ionization fraction near ionization-front (I-front), and therefore alter H_2 abundance. Also, diffuse radiation can erode neutral shadows behind dense clumps. Such erosion is significant to elucidate the

★E-mail: kenji.hasegawa@obspm.fr (KH); umemura@ccs.tsukuba.ac.jp (MU)

cosmic reionization process. To treat the diffuse radiation properly, the acceleration of radiation transfer solver is indispensable.

In this paper, we present a novel radiation transfer solver for an SPH scheme, START, with the tree-based acceleration of the RT. The paper is organized as follows. In Section 2, we describe the algorithm in detail. In Section 3, we test the new scheme by comparing with a previous scheme, for the propagation of ionization fronts around multiple sources. In Section 4, we demonstrate the impacts of diffuse recombination photons by solving the transfer of diffuse radiation. Section 5 is devoted to the conclusions. Some discussion on the related topics is also given there.

2 CODE DESCRIPTION

2.1 Smoothed particle hydrodynamics

The SPH part in our scheme basically follows Monaghan (1992). The density is described as

$$\rho_i = \sum_j m_j W(\boldsymbol{r}_{ij}, h_i), \tag{1}$$

where $m_j, \boldsymbol{r}_{ij}, h_i$ and W are the mass of jth particle, the distance between ith particle and jth particle, the smoothing length of ith particle and the kernel function, respectively. As for the kernel function, we use the standard spline form. The equation of motion for each SPH particle i is given by

$$\frac{\mathrm{d}\boldsymbol{v}_i}{\mathrm{d}t} = \boldsymbol{g}_i - \sum_j m_j \left(\frac{P_i}{\rho_i^2} + \frac{P_j}{\rho_j^2} + \Pi_{ij} \right) \nabla \bar{W}_{ij}, \tag{2}$$

where $\boldsymbol{g}_i$ is the gravitational acceleration and $P_{i(j)}$ is the pressure of $i(j)$th particle. Π_{ij} is the artificial viscosity for which we use the Monaghan-type viscosity (Monaghan & Gingold 1983; Monaghan 1992). $\bar{W}_{ij}$ is the symmetrized kernel given by

$$\bar{W}_{ij} = \frac{1}{2}[W(\boldsymbol{r}_{ij}, h_i) + W(\boldsymbol{r}_{ij}, h_j)] \tag{3}$$

(Hernquist & Katz 1989). In our scheme, the gravitational force on each SPH particle is calculated by using Barnes–Hut Tree algorithm (Barnes & Hut 1986).

As for the equation of energy, symmetric forms have been frequently used (Monaghan & Gingold 1983; Hernquist & Katz 1989). However, it is known that symmetric forms sometimes give rise to negative temperatures around a shock front (Benz 1990). Hence, we employ an asymmetric form for the equation of energy to avoid an unphysical behaviour around a shock. Such an asymmetric form has been employed so far by several authors (Steinmetz & Muller 1993; Umemura 1993; Thacker et al. 2000), where the energy equation is given by

$$\frac{\mathrm{d}u_i}{\mathrm{d}t} = -\frac{\Lambda_i - \Gamma_i}{\rho_i} + \sum_j m_j \left(\frac{P_i}{\rho_i^2} + \frac{1}{2}\Pi_{ij} \right) \boldsymbol{v}_{ij} \cdot \nabla_i \bar{W}_{ij}, \tag{4}$$

with the cooling rate Λ_i and the heating rate Γ_i. This form conserves energy well (Benz 1990; Thacker et al. 2000). In our calculations, the error of energy conservation is always less than 1 per cent. The energy equation is consistently solved with the RT of UV photons and the non-equilibrium chemistry.

2.2 Radiative transfer

2.2.1 RSPH ray-tracing

The ray-tracing algorithm in our scheme is similar to that adopted by Susa (2006), except for the tree-based acceleration that we newly

implement. Here, we briefly explain the RSPH scheme developed by Susa (2006).

The steady RT equation is given by

$$\frac{\mathrm{d}I_\nu}{\mathrm{d}\tau_\nu} = -I_\nu + S_\nu, \tag{5}$$

where I_ν, τ_ν and S_ν are the specific intensity, the optical depth and the source function, respectively. The equation has the formal solution given by

$$I_\nu(\tau_\nu) = I_{\nu,0}\mathrm{e}^{-\tau_\nu} + \int_0^{\tau_\nu} S_\nu(\tau_\nu')\mathrm{e}^{-\tau_\nu + \tau_\nu'}\mathrm{d}\tau_\nu', \tag{6}$$

where $I_{\nu,0}$ is the specific intensity at $\tau_\nu = 0$, and τ_ν' is the optical depth at a position along the ray. In order to reduce the computational cost, so-called on-the-spot approximation is employed (Spitzer 1978), where recombination photons are assumed to be absorbed on the spot. Therefore, in this approximation, the transfer of diffuse radiation is not solved. According to the on-the-spot approximation, equation (6) is simply reduced to

$$I_\nu(\tau_\nu) = I_{\nu,0}\mathrm{e}^{-\tau_\nu}. \tag{7}$$

Hence, the specific intensity at a position with τ_ν can be evaluated without any iterative method for diffuse radiation.

In Fig. 1, the method for integrating an optical depth in RSPH scheme is schematically shown. The optical depth from the radiation source to the target SPH particle can be approximately evaluated by

$$\tau_{\mathrm{target}} = \tau_{\mathrm{up}} + \Delta\tau, \tag{8}$$

where τ_{up} is the optical depth from the radiation source to the upstream SPH particle that is a member of neighbours of the target particle and the closest to the light ray (in other words, having the smallest angle ϕ). $\Delta\tau$ is the optical depth between the target particle and the intersection of the light ray with a sphere which centres the radiation source and also includes the upstream particle (n4 in Fig. 1). If τ_{up} is evaluated in advance, we should calculate only $\Delta\tau$. Here, $\Delta\tau$ is evaluated as

$$\Delta\tau = \sigma\Delta l \left(\frac{n_{\mathrm{target}} + n_{\mathrm{up}}}{2} \right), \tag{9}$$

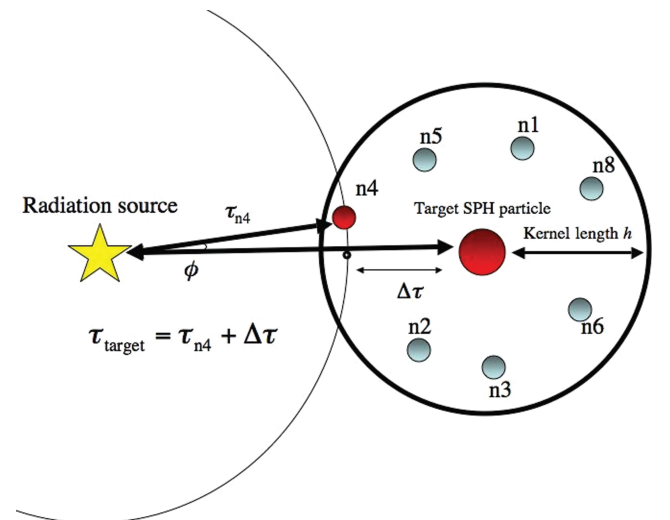

Figure 1. The method for the ray-tracing adopted in RSPH scheme is schematically shown. The large filled circle indicates the target particle to which the optical depth from the radiation source is evaluated. Smaller filled circles around the target particle indicate particles in the neighbour list of the target particle.

where σ, Δl, n_{target} and n_{up} are the cross-section, the distance between the intersection and the target particle, the number density at the position of the target particle and the number density at the position of the upstream particle, respectively.

In such a method, we have to know the optical depth of the upstream particle in advance. If we calculate τ_{up} by the integration along the light ray, the computational cost is roughly proportional to $N_p^{1/3}$, where N_p is the total number of SPH particles. Hence, the total computational cost is

$$T_{\text{calc}} \propto N_p^{1/3} N_p N_s, \tag{10}$$

where N_s is the number of radiation sources. But, if we utilize the optical depths for SPH particles in order of distance from the radiation source, only one SPH particles is used for the new optical depth evaluation. Then, the computational cost can be alleviated to

$$T_{\text{calc,RSPH}} \propto N_p N_s. \tag{11}$$

None the less, this dependence leads to enormous computational cost, if we consider numerous radiation sources. Especially, to treat the diffuse scattering photons, N_s should be equal to N_p, since all SPH particles are emission sources. Then, the computational time is proportional to N_p^2. Hence, to treat diffuse radiation, further acceleration is indispensable.

2.2.2 START: SPH with tree-based acceleration of radiative transfer

Here, we propose a new ray-tracing method designed to solve the radiation transfer for numerous radiation sources. The procedure of the new scheme is schematically shown in Fig. 2. For simplicity, the procedure is shown in 2D space, although the scheme is implemented in 3D space. The new scheme is based on oct-tree structure, which is widely used for the gravitational force calculations.

First, we construct the oct-tree structure for the distributions of radiation sources, where cubic cells are hierarchically subdivided into eight subcells. This procedure continues until each cell contains only one radiation source. As the next step, we reduce the effective number of the radiation sources for a target particle i, using the oct-tree structure. If a cell of level n is sufficiently distant from the target particle i, the radiation sources in the cell are regard as one virtual bright source located at the centre of luminosity in the cell. Practically, if the following condition is satisfied, the cell is regarded to contain one virtual bright source:

$$\frac{l_{\text{cell}}^n}{d^n} \leq \theta_{\text{crit}}, \tag{12}$$

Figure 2. The new ray-tracing method based on oct-tree structure is schematically shown. Each star and circle, respectively, indicates a radiation source and an SPH particle. In the first step, the tree structure for the distributions of radiation sources is constructed. In the second step, a list of SPH particles satisfying the same level of conditions (12) and (13) is produced for each virtual radiation source. In the lower right panel, particles in a list of a virtual radiation source are indicated by circles filled with the same colour as the owner source of the list. In the third step, optical depths from virtual sources to particles in the lists are evaluated in the same manner as Fig. 1.

$$\frac{l_{\text{cell}}^{n-1}}{d^{n-1}} > \theta_{\text{crit}}, \qquad (13)$$

where l_{cell}^n is the size of the nth level cell, d^n is the distance from the target particle to the closest edge of the cell and $n-1$ indicates the parent cell of the nth level cell. θ_{crit} is the tolerance parameter, which regulates the accuracy of resulting radiation fields. Of course, such a judgement is done not only for n and $n-1$ levels but also lower level cells, such as $n-2, n-3, \dots$, as well. Therefore, the effective number of radiation sources for a target particle can be dramatically reduced. In the present scheme, the luminosity of a virtual bright source in the nth level cell is simply given by

$$L = \sum_j L_j, \qquad (14)$$

and the position is determined by

$$\boldsymbol{r} = \frac{\sum_j L_j \boldsymbol{r}_j}{\sum_j L_j}, \qquad (15)$$

where L_j and $\boldsymbol{r}_j$ are the original luminosity and position of radiation source j in the cell, respectively. In some situations, the evaluation with the SPH kernel as

$$L = \frac{\sum_j L_j W(\boldsymbol{r} - \boldsymbol{r}_j)}{\sum_j W(\boldsymbol{r} - \boldsymbol{r}_j)},$$

or

$$L = \sum_j \frac{m_j}{\rho_j} L_j W(\boldsymbol{r} - \boldsymbol{r}_j)$$

are other possibilities. Especially, the latter may be a reasonable choice for the diffuse radiation for which all SPH particles are emitters.

Each virtual radiation source has a list of SPH particles which correspond to the same level of tree satisfying conditions (12) and (13). The list can be easily produced by using the tree structure for the distributions of SPH particles that has been already constructed to compute gravitational forces. The optical depth towards an SPH particle in the list is evaluated in order of distance from the radiation source by using equation (8). But, if an SPH particle is located on the boundary of the domain that the particles in the list compose, the particle does not know τ_{up}. Therefore, we have to integrate the optical depth towards the particle along the light ray from the virtual source.

By this tree-based algorithm, the number of radiation sources can be dramatically reduced to the order of $\log N_s$. Hence, with the new method, the computational cost is given by

$$T_{\text{calc,START}} \propto N_p \log N_s. \qquad (16)$$

Such weak dependence on N_s allows us to solve RT for diffuse photons emitted by all SPH particles as well as multiple sources. It is noted that the new ray-tracing method accords with RSPH ray-tracing in the case of $\theta_{\text{crit}} = 0$ or $N_s = 1$.

The accuracy of the new scheme depends on the value of θ_{crit}. We can easily guess that the new scheme is quite accurate in the optically thick limit, since the contributions of distant sources become negligible. In the optically thin limit, we can take θ_{crit} similar to that used in the gravity calculation, since the radiation flux is proportional to the gravity in this limit. For general cases, we discuss what value of θ_{crit} should be taken in Section 3.

3 COMPARISON BETWEEN RSPH AND START

3.1 Test calculations for the transfer of radiation from multiple sources

As mentioned above, the accuracy and the computational time depend on the tolerance parameter θ_{crit} in START. Hence, we should choose the parameter so as to achieve reasonable accuracy without vast computational cost. The best way to examine the accuracy is to compare simulation results with analytic solutions. Unfortunately, when multiple radiation sources exist, it is hard to obtain analytic solution. Therefore, we compare our results with other results simulated with a reliable scheme. Here, we use the results by RSPH ray-tracing method, since the RSPH scheme is already tested for a standard problem and the ionization structure obtained by RSPH is well concordant with analytic solutions as shown in Iliev et al. (2006) and Susa (2006).

First, we perform tests for numerous sources, under the on-the-spot approximation. We calculate the expansion of ionized regions around multiple UV sources. In the radiation hydrodynamic process of primordial gas, not only the ionization of hydrogen but also the photodissociation of hydrogen molecules H_2 is important. Hence, we solve also H_2 chemistry (see Appendix A) and H_2 photodissociation with a shielding function (see Appendix B). We use 128^3 SPH particles and 1024 radiation sources in all test calculations in this section.

3.1.1 Test 1 – Propagation of ionization fronts in an optically thick medium

As the first test, we consider multiple ionizing sources in a neutral, uniform medium with hydrogen number density of $n_H = 10^{-3}$ cm^{-3} and an initial gas temperature of 100 K. The simulation box size is 132 kpc in linear scale. Here, a static medium is assumed, and therefore no hydrodynamics is solved. The optical depth at the Lyman limit frequency initially is ~ 20 for mean particle separation. The radiation sources are randomly distributed, and simultaneously radiate UV radiation when each simulation starts. Each UV source has the blackbody spectrum with effective temperature of $T_{\text{eff}} = 10^5$ K and emits ionizing photons per second of $\dot{N}_\gamma = 5 \times 10^{48}$ s^{-1}. The Strömgren radius is analytically given by

$$R_s = \left(\frac{3\dot{N}_\gamma}{4\pi n_H^2 \alpha_B} \right)^{1/3}, \qquad (17)$$

where α_B is the recombination coefficient to all excited levels of hydrogen. In the present test, the Strömgren radius for each radiation source is 5.4 kpc, if the H II regions around sources are not overlapped. Simulations are performed until the time $t = 4.0 t_{\text{rec}}$, where t_{rec} is the recombination time defined by $t_{\text{rec}} \equiv 1/(n_H \alpha_B)$.

In Fig. 3, the distributions of temperature and ionization fractions are compared between RSPH and START with $\theta_{\text{crit}} = 1$. In both simulations, individual H II regions gradually expand and finally overlap with each other. As shown in the figure, the results are almost identical between RSPH and START at any evolutionary stage. In order to see the dependence on θ_{crit} quantitatively, in Fig. 4 we plot the volume fractions of ionized and neutral components (upper panels) and the temperature (lower panels) for $\theta_{\text{crit}} = 0.6, 1.0$ or 1.4. Here, the results by RSPH are also shown. As for ionized and neutral gas fractions, there is little disagreement among different θ_{crit}. In the volume fraction of temperature, there are a slight discrepancy only in low-temperature regions. The discrepancy increases with
Figure 3. Test 1 – Propagation of ionization fronts around multiple sources in an optically thick medium, which is assumed to be static and uniform. The hydrogen number density is $n_{\rm H} = 10^{-3}\,{\rm cm}^{-3}$ and an initial gas temperature is 100 K. The simulation box size is 132 kpc in linear scale. Upper panels show the temperature, where left three panels are the results by RSPH and right three panels are the results by START with $\theta_{\rm crit} = 1$. Lower panels show ionization fraction in a slice through the mid-plane of the simulation box. Here, the results at three different times $t = 0.5t_{\rm rec}$, $t = 1.0t_{\rm rec}$ and $t = 4.0t_{\rm rec}$ are shown, where $t_{\rm rec}$ is the recombination time.
Figure 4. Dependence on the tolerance parameter $\theta_{\rm crit}$ for Test 1. In upper panels, the volume fractions of ionized and neutral gas are respectively shown by solid and dashed lines, at $t = 0.5t_{\rm rec}$, $t = 1.0t_{\rm rec}$ and $t = 4.0t_{\rm rec}$. In each panel, lines from bottom to top show the results by RSPH, START with $\theta_{\rm crit} = 0.6$, $\theta_{\rm crit} = 1.0$, and $\theta_{\rm crit} = 1.4$, respectively. Lower panels show the volume fraction of temperature.

increasing $\theta_{\rm crit}$. But, in ionized regions ($T > 10^4$ K), the results by START agree well with RSPH results even for $\theta_{\rm crit} = 1.4$.

3.1.2 Test 2 – Propagation of ionization fronts in an optically thin medium

In the algorithm of START, a test for relatively optically thin medium is important, since the radiation from distant sources contribute significantly to ionization structure. Therefore, we carry out a test calculation, where the initial gas density is $n_{\rm H} = 10^{-5}\,{\rm cm}^{-3}$, which is 100 times lower than that in Test 1. The mean optical depth for SPH particle separation is ~0.2. Each radiation source is assumed to have $5 \times \dot{N}_\gamma = 10^{44}\,{\rm s}^{-1}$, so that the corresponding Strömgren radius is the same as that in Test 1. The positions of sources are the same as those in Test 1.

In Fig. 5, the distributions of temperature and ionization fractions are compared between RSPH and START with $\theta_{\rm crit} = 1$. Here, the early phase ($0.5t_{\rm rec}$), the expanding phase ($1.0t_{\rm rec}$) and the final equilibrium phase ($4.0t_{\rm rec}$) are shown. Similar to Test 1, each H II region gradually expands and finally overlap each other. However, H II regions show more bleary structure compared to Fig. 3. Such a difference originates from the fact that the initial mean optical depth is 100 times smaller than that in the Test 1, and each shape of ionization front becomes vaguer.

Figure 5. Test 2 – Propagation of ionization fronts around multiple sources in an optically thin medium. The same quantities as in Fig. 3 are shown.
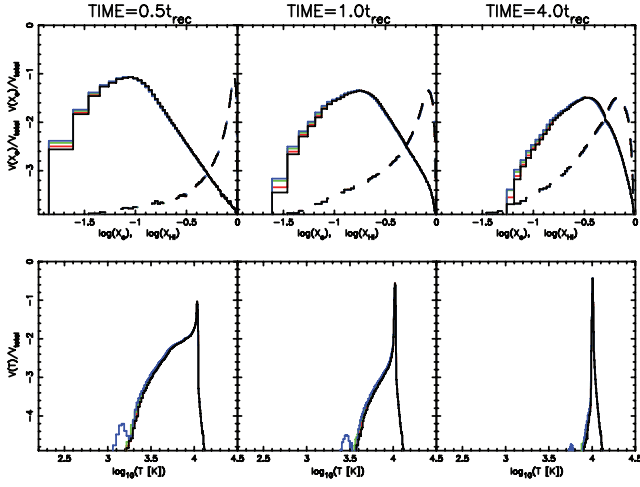

Figure 6. Same as Fig. 4, except for Test 2.

In Fig. 6, we plot the volume fractions of ionized and neutral components (upper panels) and the temperature (lower panels) for $\theta_{\rm crit} = 0.6, 1.0$ or 1.4. The results by START with $\theta_{\rm crit} = 0.6$ and 1.0 are well concordant with RSPH results. In the case of $\theta_{\rm crit} = 1.4$, on the other hand, a small peak appears at several 10^3 K in the volume fraction of the temperature. Hence, $\theta_{\rm crit} \lesssim 1$ seems to give more reliable results in this case.

3.1.3 Test 3 – Expansion of H II regions with hydrodynamics

Here, we perform a test calculation coupled with hydrodynamics. The radiation transfer of UV photons is consistently solved with hydrodynamics. The initial gas density and temperature are set to be the same as those in Test 1. The luminosities and positions of radiation sources are also the same as those in Test 1. Therefore,
Figure 8. Dependence on the tolerance parameter $\theta_{\rm crit}$ for Test 3. In upper panels, the volume fractions of ionized and neutral gas are, respectively, shown by solid and dashed lines, at $t = 0.5t_{\rm rec}$, $t = 1.0t_{\rm rec}$ and $t = 4.0t_{\rm rec}$. In each panel, lines from bottom to top show the results by RSPH, START with $\theta_{\rm crit} = 0.6, \theta_{\rm crit} = 1.0$ and $\theta_{\rm crit} = 1.4$, respectively. Lower panels show the volume fraction of temperature.

the difference between this test and Test 1 is solely whether hydrodynamics is coupled or not.

In Fig. 7, the results by START with $\theta_{\rm crit} = 1.0$ are compared with the results by RSPH in terms of hydrogen number density, temperature and ionization fractions. As shown in this figure, there is no distinct difference between RSPH and START, even if we include hydrodynamics. In Fig. 8, we show the dependence on $\theta_{\rm crit}$ in terms of volume fractions of ionized and neutral components (upper panels), and temperature (lower panels) at three different phases $0.5t_{\rm rec}, 1.0t_{\rm rec}$ and $4.0t_{\rm rec}$. As shown in the figure, the volume fractions for all simulations look well concordant. In Fig. 9, we show

Figure 7. Test 3 – Expansion of H II regions with hydrodynamics around multiple sources. The initial conditions are the same as those in Test 1. Upper panels depict the hydrogen number density, where left three panels are the results by RSPH and right three panels are the results by START with $\theta_{\rm crit} = 1$. Middle panels show the temperature. Lower panels show ionization fractions in a slice through the mid-plane of the simulation box. Here, the results at three different times $t = 0.5t_{\rm rec}$, $t = 1.0t_{\rm rec}$ and $t = 4.0t_{\rm rec}$ are shown, where $t_{\rm rec}$ is the recombination time.
Figure 9. Relative differences in the temperature (upper panels) and the ionized gas fraction (lower panels) between START and RSPH at the epoch $t = 4.0t_{rec}$. From left to right column, the relative differences between RSPH and START with $\theta_{crit} = 0.6$, $\theta_{crit} = 1.0$ and $\theta_{crit} = 1.4$ are shown.

relative differences in temperature (upper panels) and ionized gas fraction (lower panels) between START and RSPH. Here, three START simulations with $\theta_{crit} = 0.6, 1.0$ and 1.4 are compared with RSPH at $t = 4.0t_{rec}$. The distributions are given for the mid-plane of the computational box. The relative difference of a physical quantity is evaluated as

$$\Delta Q = \frac{|Q_{START} - Q_{RSPH}|}{Q_{RSPH}}, \quad (18)$$

where Q_{START} and Q_{RSPH} are the quantities obtained by START and by RSPH, respectively.

As seen in Fig. 9, the relative differences increase according as the tolerance parameter becomes larger. Moreover, the relative differences in the neutral regions are higher than those in the highly ionized region, since the physical quantities in such neutral regions are sensitive to the incident ionizing flux. Fig. 9 shows that if we choose the tolerance parameter of $\theta_{crit} \lesssim 1.0$, the relative differences become as small as $\lesssim 10^{-2}$ everywhere.

3.2 Computational time

In this section, we show how RT calculations are accelerated by the new ray-tracing method. The calculations have been done with one Xeon processor (12Gflops). The calculation time is measured in Test 3 with varying the number of radiation sources. The calculations are done until $t = 1.0t_{rec}$ with $\sim$30–40 time-steps. In Fig. 10, the mean computational time per step is shown as a function of the radiation source number. In this figure, the computational time by RSPH is denoted by black line, while that by START with $\theta_{crit} = 0.6, 0.8$ and 1.0 are denoted by red dashed, solid and dotted lines, respectively. The SPH particle number is $N_p = 128^3$ or 64^3. In the case with $N_p = 64^3$, START is always faster than RSPH. This actually comes from the reduction of the effective number of radiation sources. In the case of $N_p = 128^3$, START is faster than RSPH as long as $N_s > 10$. The calculation with $N_s = 1024$ by START is roughly 30 times faster than that by RSPH, and we find that the results obtained by START are well concordant with those by RSPH. The START allows the acceleration by $N_p \log N_s$ for a large number of sources, as anticipated. However, START is a bit slower than RSPH for $N_s < 10$. In the START scheme, each radiation source (cell) has a list of SPH particles, to which optical depths are evaluated. When we calculate the optical depths, we also have to evaluate optical depths to some SPH particles that are not in the list. The time for calculating this

Figure 10. Average computational time per one step is shown as a function of number of radiation sources for SPH particles of $N_p = 128^3$ and $N_p = 64^3$. The computational times of START and RSPH are denoted by thick and thin lines, respectively. As for START, the calculations with $\theta_{crit} = 0.6, 0.8$ and 1.0 are indicated by dashed, solid and dotted lines, respectively.

additional part increases accordingly as the number of SPH particles increases. In addition, the effective source number is hardly reduced in the case of $N_s \sim 10$. Such an increase of computational time is noticeable for $N_p = 128^3$ run, but not in $N_p = 64^3$ run. Anyway, the acceleration by START allows us to treat a large number of sources.

4 RADIATIVE TRANSFER OF DIFFUSE RADIATION

In the previous sections, we have shown the acceleration by START for multiple radiation sources. Here, we present the effectiveness of START when we include diffuse radiation, where all SPH particles should be emitting sources. We concentrate on the photoionization problem again and include diffuse recombination photons.

4.1 Physical process

To consider the transfer of recombination photons, we adopt the recombination coefficient to all bound levels of hydrogen $\alpha_A(T)$, instead of that to all excited levels of hydrogen $\alpha_B(T)$ in the on-the-spot approximation. We solve the transfer of recombination photons from each SPH particle to all other particles by using equation (7) and oct-tree structure. The number of recombination photons emitted per unit time by an SPH particle j is expressed by

$$\dot{N}_{rec, j} = \alpha_1(T_j)n_{e, j}n_{p, j}V_j, \quad (19)$$

where T_j, n_e, n_p and V_j are the temperature, the electron number density, the proton number density and the volume of $j$the particle, respectively. $\alpha_1(T)$ is the recombination coefficient to the ground state of hydrogen, i.e. $\alpha_1(T) = \alpha_A(T) - \alpha_B(T)$. The emitted energy per one recombination is $\sim h\nu_L + kT_j$, where h and k are, respectively, the Planck constant and the Boltzmann constant. The temperature of photoionized gas is typically $\sim 10^4$ (e.g. Umemura & Ikeuchi 1984; Thoul & Weinberg 1996), and therefore $h\nu_L \gg kT_j$. Thus, the number of recombination photons emitted by particle j per unit time and solid angle is approximately given by

$$\dot{n}_{\nu, j} \approx \begin{cases} \dot{N}_{rec, j}/4\pi\delta\nu & \cdots \ \nu_L \leq \nu \leq \nu_L + \delta\nu, \\ 0 & \cdots \ \text{otherwise}, \end{cases} \quad (20)$$

where $\delta\nu = kT_j/h$. As described in Section 2, if a cell is far enough from a target particle, SPH particles emitting recombination photons in the cell are regarded as one bright emitter. The position and the recombination photon number of the bright source labelled α are respectively determined by

$$\boldsymbol{r}_\alpha = \frac{\sum_j \dot{N}_{\text{rec},j}\boldsymbol{r}_j}{\sum_j \dot{N}_{\text{rec},j}}, \tag{21}$$

$$\dot{n}_{\nu,\alpha} = \frac{\sum_j \dot{N}_{\text{rec},j}}{4\pi\delta\bar{\nu}}. \tag{22}$$

Here $\delta\bar{\nu}$ is defined by

$$\delta\bar{\nu} = \frac{k}{h}\frac{\sum_j \dot{N}_{\text{rec},j}T_j}{\sum_j \dot{N}_{\text{rec},j}}. \tag{23}$$

As for the recombination photon number for virtual sources, using another form by the SPH kernel interpolation instead of equation (22) might be a reasonable way. Using equation (7) instead of equation (6), the photoionization rate caused by αth radiation source on ith particle is given by

$$k_\alpha = n_{\text{H\,I}}(\boldsymbol{r}_i) \int \int_{\nu_L}^{\nu_L+\delta\bar{\nu}} \dot{n}_{\nu,\alpha} e^{-\tau_{\nu,\alpha}} \sigma_\nu \, d\nu \, d\Omega. \tag{24}$$

Here the integration with respect to solid angles is done by considering the effect of geometrical dilution. The total photoionization rate at $\boldsymbol{r}_i$ is given by

$$k_{\text{ion}} = k_{\text{self}} + k_{\text{other}}, \tag{25}$$

where k_{self} is the contribution from ith particle itself and k_{other} is the contributions from all emitting particles except for $i$the particle. k_{other} is given by

$$k_{\text{other}} = \sum_\alpha k_\alpha. \tag{26}$$

Applying equation (6) and assuming the isotropic radiation field around ith particle, k_{self} is given by

$$k_{\text{self}} = 4\pi n_{\text{H\,I}} \int_{\nu_L}^{\nu_L+\delta_\nu} \int_0^{\tau_\nu} \frac{S_\nu}{h\nu}\sigma_\nu e^{-\tau_\nu+\tau_\nu'} \, d\tau_\nu' \, d\nu, \tag{27}$$

where τ_ν is the optical depth from the edge to the centre of the particle, which is given by

$$\tau_\nu = \sigma_\nu n_{\text{H\,I}} \left(\frac{3V}{4\pi}\right)^{1/3}. \tag{28}$$

In addition, the source function S_ν can be provided by

$$S_\nu = \begin{cases} \frac{h\nu\alpha_1(T)n_e n_p}{4\pi n_{\text{H\,I}}\sigma_\nu\delta\nu} & \cdots \ \nu_L \le \nu \le \nu_L + \delta\nu, \\ 0 & \cdots \text{ otherwise,} \end{cases} \tag{29}$$

Here the source function can be regarded as almost constant near the centre of particle i. As a result, equation (27) can simply be given by

$$k_{\text{self}} = \int_{\nu_L}^{\nu_L+\delta_\nu} \frac{\alpha_1(T)}{\delta\nu}n_e n_p(1 - e^{-\tau_\nu}) \, d\nu. \tag{30}$$

Note that equation (25) accords with $\alpha_1(T)n_e n_p$, if the medium is very opaque everywhere. It means that the 'net' recombination coefficient corresponds to α_B in that case. We also evaluate the photoheating rate caused by the recombination photons in a similar way. The photoheating due to the recombination photons emitted by ith particle itself and by all other particles are, respectively, given by

$$\Gamma_{\text{self}} = \int_{\nu_L}^{\nu_L+\delta_\nu} \frac{\alpha_1(T)}{\delta\nu}n_e n_{\text{H}^+}h(\nu - \nu_L)(1 - e^{-\tau_\nu}) \, d\nu, \tag{31}$$

and

$$\begin{aligned} \Gamma_{\text{other}} = n_{\text{H\,I}} \sum_\alpha \int \int_{\nu_L}^{\nu_L+\delta\bar{\nu}} \dot{n}_{\nu,\alpha} \\ \times h(\nu - \nu_L)e^{-\tau_{\nu,\alpha}}\sigma_\nu \, d\nu \, d\Omega. \end{aligned} \tag{32}$$

Finally, the total photoheating rate due to the recombination radiation for each SPH particle is given by

$$\Gamma_{\text{heat}} = \Gamma_{\text{self}} + \Gamma_{\text{other}}. \tag{33}$$

4.2 Test calculations for the transfer of recombination photons

In this section, we explore the effect of recombination photons by performing some test calculations. All simulations in this section are performed with 128^8 SPH particles. The transfer of recombination photons is solved by START with $\theta_{\text{crit}} = 0.8$.

4.2.1 Test 4 – Expansion of an H II region in a static medium

In this test, we simulate an expansion of an H II region in a uniform static medium. The initial physical parameters of this test are the same as those of Test 2 in Cosmological Radiative Transfer Comparison Project (Iliev et al. 2006), where the hydrogen number density is $n_{\text{H}} = 10^{-3}$ cm^{-3}, the gas temperature is $T = 10^2$ K and the ionization fraction is 1.2×10^{-3}. The computational box is 13.2 kpc in linear scale. One radiation source with an effective temperature $T_{\text{eff}} = 10^5$ K and the number of ionizing photons per unit time as $\dot{N}_\gamma = 5 \times 10^{48}$ s^{-1} is set up at the centre of the computational box ($[x, y, z] = [0, 0, 0]$ kpc). The Stromömgren radius estimated by equation (17) is 5.4 kpc. The simulation is performed until 500 Myr, which roughly corresponds to 4 t_{rec}.

In Fig. 11, we show the neutral fractions in a slice through the mid-plane of the computational box at a fast expanding phase ($t = 30$ Myr), a slowing-down phase ($t = 100$ Myr) and the final

Figure 11. Test 4 – Expansion of an H II region in a static medium. Upper three panels are the results by the on-the-spot approximation, while lower three panels are the results by solving the transfer of diffuse recombination photons. The neutral fractions in a slice through the mid-plane of the computational box are shown at $t = 30$ Myr (left-hand panels), $t = 100$ Myr (middle panels) and $t = 500$ Myr (right-hand panels).
Figure 12. The temperature distributions in Test 4.

equilibrium phase ($t = 500\,$Myr). Fig. 12 gives the temperature distributions. In these figures, we compare the results by solving the transfer of recombination photons with those by on-the-spot approximation. Although the difference between these results is not large at $t = 30\,$Myr or $t = 100\,$Myr, the difference is distinct at later phase at the final equilibrium phase ($t = 500\,$Myr). The ionized region simulated with the transfer of recombination photons is more extended than that simulated with the on-the-spot approximation.

In order to confirm whether the transfer of recombination photons is correctly solved, we compare the results obtained by START with those by a 1D spherical symmetric radiative hydrodynamics (RHD) code developed by Kitayama et al. (2004) in which the transfer of recombination photons is solved. In 1D RHD simulations, 600 gas shells are used. In Fig. 13, we show the radial profiles of the ionized fraction, the neutral fraction and the temperature at each evolutionary phase. As shown in this figure, the results of the 3D RHD and 1D RHD simulations are well consistent with each other. The difference between the profiles in the full transfer and the on-the-spot approximation appears in moderate regions in which the neutral fractions are $x \sim 0.1$. In these regions, the ionized fractions calculated by solving the full transfer are slightly higher than those calculated by assuming the on-the-spot approximation. On the other hand, near the radiation source, the neutral fractions obtained by the
full transfer are slightly lower, in contrast to the moderate ionized regions. This originates from the fact that α_A is greater than α_B.

4.2.2 *Test 5 – Expansion of an H II region with hydrodynamics*

This test is similar to Test 4, but here hydrodynamics is consistently solved with the RT. The initial physical parameter set of the test is the same as those of Test 5 in Cosmological Radiative Transfer Comparison Project (Iliev et al. 2009), where the initial gas density and temperature are $10^{-3}\,$cm^{-3} and $100\,$K, respectively. The size of the computational box is 30 kpc in linear scale. A radiation source with $T_{eff} = 10^5\,$K and $\dot{N}_\gamma = 5 \times 10^{48}\,$s^{-1} is set at the centre of the computational box ($[x, y, z] = [0, 0, 0]$ kpc).

The neutral fractions, the temperature and the hydrogen number density in a slice through the mid-plane of the computational box are shown in Figs 14, 15 and 16, respectively. In these figures, we show the distributions of these quantities at three different evolutionary phases. In the first phase, R-type ionization front (I-front) rapidly propagates ($t = 30\,$Myr). In the second phase, the transition of I-front from R-type to D-type occurs ($t = 100\,$Myr), and finally in the third phase, D-type I-front preceded by a shock propagates ($t = 500\,$Myr). These figures show that if hydrodynamics is coupled, the resultant ionization structure is in a quite good agreement with the results by the on-the-spot approximation.

Figure 14. Test 5 – Expansion of an H II region with hydrodynamics. Upper three panels are the results by the on-the-spot approximation, while lower three panels are the results by solving the transfer of diffuse recombination photons. The neutral fractions in a slice through the mid-plane of the computational box at $t = 30\,$Myr (left-hand panels), $t = 100\,$Myr (middle panels) and $t = 500\,$Myr (right-hand panels) are shown.

Figure 13. For Test 4, radial profiles of the ionized fraction, the neutral fraction (upper row) and the temperature (lower row) at $t = 30\,$Myr, $t = 100\,$Myr and $t = 500\,$Myr are shown. The profiles obtained by 3D radiation transfer START and 1D spherical symmetric radiation transfer are indicated by thick and thin lines, respectively. Solid lines show the results by the on-the-spot approximation, while dashed lines show those by the full transfer of recombination photons.

Figure 15. The temperature distributions in Test 5.
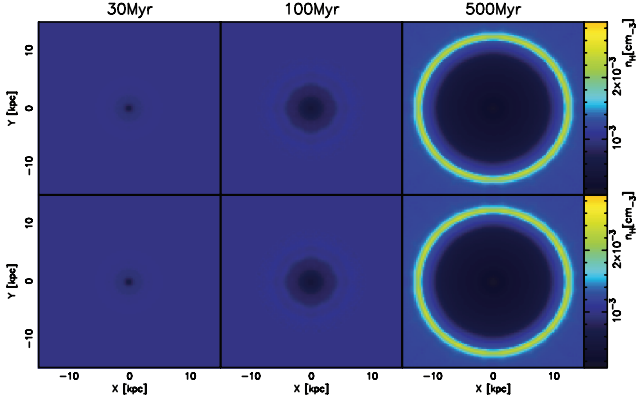

Figure 16. The hydrogen number density distributions in Test 5.

Figure 17. For Test 5, radial profiles of the ionized fraction, the neutral fraction (top row), the temperature (middle row) and the hydrogen number density (bottom row) at $t = 10\,\mathrm{Myr}$, $t = 200\,\mathrm{Myr}$ and $t = 500\,\mathrm{Myr}$ are shown. The profiles obtained by 3D radiation transfer and 1D spherical symmetric radiation transfer are indicated by thick and thin lines, respectively. Solid lines show the results by the on-the-spot approximation, while dashed lines show those by the full transfer of recombination photons.

In Fig. 17, we compare the results with a 1D RHD simulation. Here, the averaged radial profiles of the ionized fraction, the neutral fraction, the temperature and the hydrogen number density are shown at three different times $t = 10\,\mathrm{Myr}$, $t = 200\,\mathrm{Myr}$, and $t = 500\,\mathrm{Myr}$. At every phase, the profiles in 3D RHD simulations are well concordant with 1D RHD results. Similar to the case without hydrodynamics, it is found that the recombination photons slightly change the profile of ionized fraction near the I-front. On the other hand, the profile of the temperature is not strongly affected by the recombination photons. As a result, the gas dynamics does not change dramatically in this case, even if we consider the transfer of recombination photons.

4.2.3 Test 6 – Shadowing effects by dense clumps

Here, we explore the shadowing effect behind dense clumps. The physical parameters in this test is the same as those in Test 4, except

that a dense clump with the radius of $r_\mathrm{c} = 0.56$ kpc is placed at 0.8 kpc away in the x-direction from the box centre ([0.8, 0, 0] kpc). The hydrogen number density of the clump is $n_\mathrm{c} = 2.0 \times 10^{-1}\,\mathrm{cm}^{-3}$, which is 200 times higher than that in the surrounding medium of $n_\mathrm{H} = 10^{-3}\,\mathrm{cm}^{-3}$. The Strömgren radius r_s for the density of clump is given by

$$r_\mathrm{s} = \frac{F}{\alpha_\mathrm{B} n_\mathrm{H}^2}, \tag{34}$$

where F is the incident photon number flux. Assuming $T = 10^4$ K and using F at the centre of the clump, the Strömgren radius is roughly $r_\mathrm{s} \approx 0.025$ kpc. Since $r_\mathrm{c} \gg r_\mathrm{s}$, the clump is readily shielded from the incident radiation. Thus, it is expected that the ionization front is trapped in the clump and a shadow is created behind the clump.

In Figs 18 and 19, we show the resultant ionized fraction and temperature in a slice through the mid-plane of the box. In each figure, the upper panels show the result by on-the-spot approximation, while the lower panels show that by the transfer of recombination photons. The ionization front is expectedly trapped in the dense clump and a shadow is created. Under the on-the-spot approximation, only the transfer of UV photons along the radial direction from the radiation source is included. On the other hand, when we solve

Figure 18. Test 6 – Shadowing effects by a dense clump. The hydrogen number density of the clump and surrounding medium is respectively $n_\mathrm{c} = 2.0 \times 10^{-1}\,\mathrm{cm}^{-3}$ and $n_\mathrm{H} = 10^{-3}\,\mathrm{cm}^{-3}$. The clump radius is $r_\mathrm{c} = 0.56$ kpc. Upper three panels are the results by the on-the-spot approximation, while lower three panels are the results by solving the transfer of diffuse recombination photons. The neutral fraction in a slice through the mid-plane of the computational box are shown at $t = 100\,\mathrm{Myr}$ (left-hand panels), $t = 200\,\mathrm{Myr}$ (middle panels) and $t = 500\,\mathrm{Myr}$ (right-hand panels).

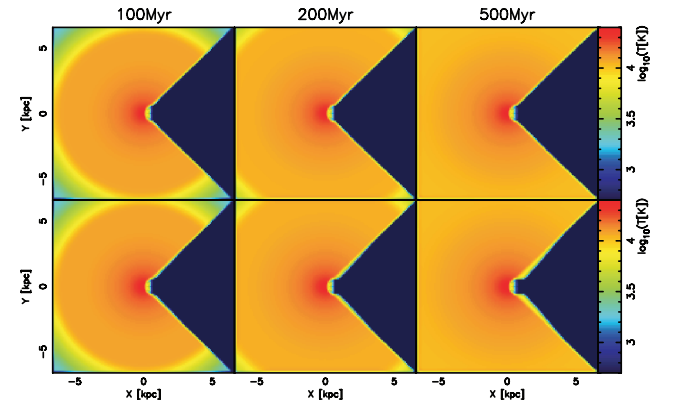

Figure 19. The temperature distributions in Test 6.

the transfer of diffuse recombination photons, the recombination photons from the other directions photoionize the shadow. We can observe such an erosion of shadow in Figs 18 and 19. But, the erosion is not so drastic in this case. It is related to the mean free path of ionizing photons. The mean free path of ionizing photons at Lyman limit frequency L_{mfp} is given by

$$L_{mfp} = 51.4 \times \left(\frac{10^{-3}\,\mathrm{cm^{-3}}}{n_H} \right)\,\mathrm{pc}. \tag{35}$$

This implies that the initial mean free path in surrounding low-density regions is approximately one-tenth of the size of clump. The size of erosion is just corresponding to the mean free path of ionizing photons. That means that in lower density of surrounding medium, the erosion is more significant.

In order to confirm the effect of the mean free path, we simulate the case in which the number density of surrounding medium is one-tenth of that in previous case. In this case, the mean free path is roughly comparable with the size of the clump. We show the ionized fraction in a slice through the mid-plane of the box in Fig. 20. The results by the on-the-spot approximation and those by the full transfer are shown in the upper panels and the lower panels, respectively. As shown in the figure, the recombination photons can gradually ionize the gas behind the clump, in contrast to the higher density case. We show the temperature distributions in Fig. 21. Owing to photoheating by the recombination photons, the gas behind the clump is heated up. Since the number density assumed here roughly corresponds to that in intergalactic medium

Figure 20. Same as Fig. 18, but for the lower density of surrounding medium as $n_H = 10^{-4}\,\mathrm{cm^{-3}}$.

Figure 21. The temperature distributions in the case of Fig. 20.

**Figure 22.** Ionization of a medium containing small clumps. The hydrogen number density and radius of each clump are $n_c = 2.0 \times 10^{-1}\,\mathrm{cm^{-3}}$ and $r_c = 10\,\mathrm{pc}$, respectively. The number density of surrounding medium is $n_H = 10^{-2}\,\mathrm{cm^{-3}}$. Upper three panels are the results by the on-the-spot approximation, while lower three panels are the results by solving the transfer of diffuse recombination photons. The neutral fraction in a slice through the mid-plane of the computational box are shown at $t = 3\,\mathrm{Myr}$ (left-hand panels), $t = 10\,\mathrm{Myr}$ (middle panels) and $t = 20\,\mathrm{Myr}$ (right-hand panels).

at high redshifts, it is expected that the recombination photons play an important role for the reionization of the Universe.

We also demonstrate the effect of recombination photons for a medium containing multiple small clumps. In this simulation, nine dense clumps are set up on the mid-plane ($z = 0$). Each clump has the hydrogen number density of $n_c = 2.0 \times 10^{-1}\,\mathrm{cm^{-3}}$ and the radius of $r_c = 10\,\mathrm{pc}$. The number density of surrounding medium is $n_H = 10^{-2}\,\mathrm{cm^{-3}}$. These clumps are illuminated by a UV source, which is located at the box centre. The radius of each clump is comparable with the mean free path of ionizing photons. Fig. 22 shows the ionization structure under the on-the-spot approximation (upper three panels), and that resulting from the transfer of recombination photons (lower three panels). With the on-the-spot approximation, shadows by dense clumps are clearly created. In this case, UV radiation never reaches shadowed regions behind the clumps. In contrast, if the transfer of recombination photons is solved, low-density regions behind all clumps are highly ionized. Consequently, the ionization structure is dramatically changed, compared to the on-the-spot approximation.

4.3 Computational time for the transfer of diffuse photons

In Fig. 23, we show the average computational time per step for the simulations in Test 5 as a function of the number of SPH particles. The calculations are performed until $t = 100\,\mathrm{Myr}$ with $\sim$10–30 time-steps. In this figure, RSPH, START and ART (grid-based accelerated RT) are compared. As mentioned above, in RSPH ray-tracing method, the transfer of ionizing photons from each SPH particle to all other SPH particles are solved. Therefore, the computational time should follow equation (11). On the other hand, in START scheme, distant radiation sources are regarded as one virtual bright source. Hence, the calculation time should follow equation (16). Note that the density distribution is nearly uniform at the initial phase, but becomes very inhomogeneous at the end of the calculation as shown in Fig. 17. None the less, the measured computational time follows equation (16), as seen in Fig. 23. It turns out that START is 100–1000 times faster than RSPH in the case of $N_p \sim 10^5$. More dramatic speed-up is expected in simulations with larger number of particles, although the degree of speed-up would be different
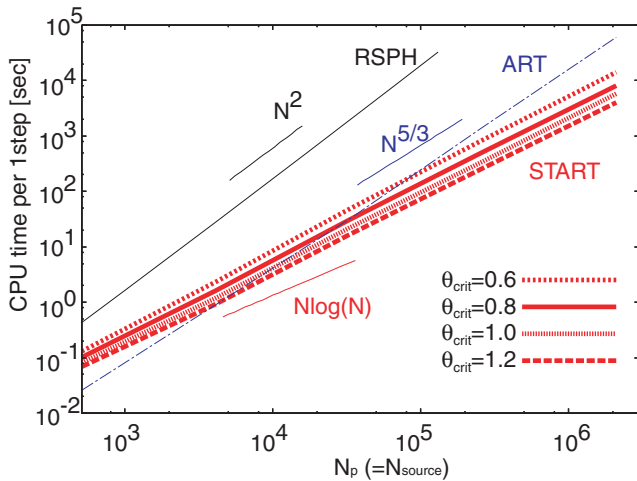

Figure 23. Computational time for solving the transfer of diffuse recombination photons is shown as a function of the particle (or grid cell) number. The computational times with START, RSPH and ART (a grid-based accelerated RT) are plotted using thick, thin solid and thin dot-dashed lines, respectively. As for START, the computational time with $\theta_{crit} = 0.6$, 0.8, 1.0 and 1.2 are indicated by short dashed, solid, dotted, and long dashed lines, respectively.

according to the distributions of particles. As shown in Fig. 23, the larger θ_{crit} is the shorter the calculation time is. The computational time is roughly scaled to θ_{crit}^{-2}.

Also, the dependence of computational time for START is better than that for a grid-based ray-tracing method, e.g. a long-characteristics method or a short-characteristics method. The details are given in Appendix C. ART is a grid-based accelerated RT scheme. The accuracy of ART is close to a long-characteristics method, and the computational cost is similar to a short-characteristics method (Iliev et al. 2006). The computational time with ART is basically proportional to $N_{grid}^{5/3}$. We also show measured calculation time of ART in Fig. 23. Actually, the calculation time of ART is roughly proportional to $N_{grid}^{5/3}$. As shown in Fig. 23, START is faster than ART, if the total particle (grid) number is greater than $\sim 10^4$.

5 CONCLUSIONS AND DISCUSSION

We have presented a novel accelerated radiation hydrodynamics scheme START, which is an SPH scheme with tree-based acceleration of radiation transfer. In this scheme, an oct-tree structure is utilized to reduce the effective number of radiation sources. The computational time by START is roughly proportional to $N_p \log N_s$, where $\log N_s$ is the radiation source number and N_p is the SPH particle number. We have shown the accuracy of START is almost equivalent to that of a previous radiation SPH scheme, if we set the tolerance parameter as $\theta_{crit} \leq 1.0$. The method presented in this paper provides a powerful tool to solve numerous radiation sources. Also, the new scheme allows us to solve the transfer of diffuse scattering photons. In this case, the computational time is proportional to $N_p \log N_p$. We have simulated the expansion of an H II region around a radiation source in an initially uniform medium. Comparing these results with 1D spherical symmetric RHD, we have confirmed that our new method correctly solve the transfer of diffuse recombination photons. In addition, we have explored the impacts of recombination photons in the case that dense clumps are irradiated by a luminous radiation source. As a result, we have found

that the recombination photons can dramatically change the ionization structure especially behind clumps, if the size of the clump is smaller than the mean free path of the recombination photons.

START is likely to be available for various astrophysical issues in which numerous radiation sources are required. One of them is the simulation of cosmic reionization. Many simulations have hitherto been widely performed (e.g. Beak et al. 2009, Iliev et al. 2007, Mellema et al. 2006, Santos et al. 2008 and Thomas et al. 2009). With START, it would be possible to trace the reionization process by solving hydrodynamics consistently coupled with the transfer of UV photons from numerous sources. Furthermore, the diffuse radiation may play an important role when we consider the impacts of UV radiation from a massive star on neighbouring medium (Ahn & Shapiro 2007; Whalen et al. 2008; Hasegawa, Umemura & Kitayama 2009a; Hasegawa et al. 2009b). We will further challenge these issues in forthcoming papers.

APPENDIX A: NON-EQUILIBRIUM CHEMISTRY

The non-equilibrium chemistry for e^-, p, H, H^-, H_2 and H_2^+ is implicitly solved by the chemical network solver in Kitayama et al. (2001). Using the evaluated optical depth and omitting the suffix i, the photoionization rate of hydrogen for each SPH particle i is given by

$$k_{\rm ion} = \sum_\alpha k_{{\rm ion},\alpha}, \qquad (A1)$$

where $k_{{\rm ion},\alpha}$ denotes the radiative contribution from radiation source α on each particle i, which is represented by

$$k_{{\rm ion},\alpha} = n_{\rm HI} \int_{\nu_{\rm L}}^\infty \int \frac{I_{\nu,\alpha} \exp(-\tau_{\nu,\alpha})}{h\nu} \sigma_\nu \, {\rm d}\Omega \, {\rm d}\nu, \qquad (A2)$$

where $n_{\rm HI}$, $\nu_{\rm L}$, $I_{\nu,\alpha}$ and σ_ν are the neutral hydrogen number density of the particle i, the Lyman limit frequency, the intrinsic specific intensity emitted from the radiation source α and the photoionization cross-section at a frequency ν. Similarly, the photoheating rate for each SPH particle i is denoted by

$$\Gamma_{\rm ion} = \sum_\alpha \Gamma_{{\rm ion},\alpha}, \qquad (A3)$$

where

$$\Gamma_{{\rm ion},\alpha} = n_{\rm HI} \int_{\nu_{\rm L}}^\infty \int \frac{I_{\nu,\alpha} \exp(-\tau_{\nu,\alpha})}{h\nu}$$
$$\times (h\nu - h\nu_{\rm L}) \sigma_\nu \, {\rm d}\Omega \, {\rm d}\nu. \qquad (A4)$$

Here the integral with respect to solid angles is done by taking into account the effect of geometrical dilution. The photodissociation rate for each SPH particle i is also given by

$$k_{\rm dis} = \sum_\alpha k_{{\rm dis},\alpha}, \qquad (A5)$$

where $k_{{\rm dis},\alpha}$ is the contribution from radiation source α, which is evaluated by using equation (B1).

APPENDIX B: H_2 PHOTODISSOCIATION

H_2 photodissociation is regulated by the transfer of Lyman–Werner (LW) band lines of H_2 molecules. The transfer of LW band is explored in detail by Draine & Bertoldi (1996), and the self-shielding function is provided. Here, we employ the self-shielding function and evaluate the photodissociation rate as

$$k_{\rm dis} = 1.13 \times 10^8 F_{\rm LW,0} f_{\rm sh} \left(\frac{N_{H_2}}{10^{14} \, {\rm cm}^{-2}} \right) {\rm s}^{-1}, \qquad (B1)$$

where

$$f_{\rm sh}(x) \equiv \begin{cases} 1, & x \leq 1 \\ x^{-3/4} & x > 1. \end{cases} \qquad (B2)$$

Here $F_{\rm LW,0}$ is the LW flux in absence of the self-shielding effect and N_{H_2} is the H_2 column density. The H_2 column density from a radiation source to the target particle is given by

$$N_{H_2,{\rm tar}} = N_{H_2,{\rm up}} + \Delta N_{H_2}, \qquad (B3)$$

where $N_{H_2,{\rm up}}$ is the column density from the radiation source to the upstream particle, and ΔH_{H_2} is given by

$$\Delta N_{H_2} = \Delta l \left(\frac{n_{H_2,{\rm up}} + n_{H_2,{\rm tar}}}{2} \right). \qquad (B4)$$

Here $n_{H_2,{\rm up}}$ and $n_{H_2,{\rm tar}}$ are the H_2 number densities at the points of the upstream particle and the target particle, respectively.

APPENDIX C: GRID-BASED RADIATIVE TRANSFER

In the case where all grids emit radiation, the specific intensity of each grid cell is evaluated by solving equation (6) along characteristics.

In a long-characteristics method, the specific intensity at each grid point is evaluated for all angular directions. Moreover, calculations of the order of $N_{\rm grid}^{1/3}$ are needed to solve the equation (6) along each light ray. Therefore, the calculation time is roughly proportional to $N_{\rm grid}^{4/3} \times N_\theta \times N_\phi$, where N_ϕ, N_θ are the number of bins for ϕ direction and θ direction, respectively. $N_\theta \sim N_\phi$ should be of the order of $\sim N_{\rm grid}^{1/3}$, since all the points in the simulation box should be irradiated by all grid points. As a result, the computational time is proportional to $N_{\rm grid}^2$.

In a short-characteristics method, the optical depth is calculated by interpolating values of segments lying along the light ray. When the transfer of recombination photons is involved, the total number of the incident rays into a computational box is $N_{\rm grid}^{2/3} \times N_\theta \times N_\theta \sim N_{\rm grid}^{4/3}$ (Nakamoto et al. 2001). In addition, calculation of the order of $N_{\rm grid}^{1/3}$ is needed for each incident ray. Therefore, the computational time of the short-characteristics method is proportional to $N_{\rm grid}^{5/3}$.

ART scheme is based on a long-characteristics method, but only parallel right rays are solved. As a result, the accuracy is close to a long-characteristics method, and the computational cost is similar to a short-characteristics method (Iliev et al. 2006). ART scheme allows us to solve the transfer of diffuse radiation. Actually, the scheme is applied to evaluate the escape fraction of ionizing photons from a high-z galaxy (Yajima et al. 2009). In the ART scheme for a simulation of diffuse radiation, the specific intensity on each segment along a light ray is calculated by using equation (6). The intensity at a grid point is obtained by the interpolation from the neighbouring light rays. The total number of the light rays is $6 \times N_{\rm grid}^{2/3} \times N_\theta \times N_\theta \sim N_{\rm grid}^{4/3}$. Thus, the calculation time for this method is proportional to $N_{\rm grid}^{5/3}$, similar to that for a short-characteristics method.
