17 **Abstract**

18 The pyrolytic reactive granulation process, yielding ceramic spherical porous granules, is simple,  
19 consisting of typical ceramic processing methods, *viz.*, wet-ball milling of powders, vacuum drying,  
20 granulation via sieving through a screen mesh, and one-step heat treatment for local reactive  
21 sintering within each granule. Here, the microstructural development of spherical porous granules  
22 was successfully visualized by *in situ* high-temperature confocal laser-scanning microscopy during  
23 the heating up to 1400°C in air. Based on the result of the *in situ* observation, a simple but powerful  
24 size-controlling process of spherical porous granules, *viz.*, multiscreen sieving after the heating was  
25 demonstrated. Nearly monodispersed spherical porous granules composed of pseudobrookite-type  
26 MgFeNbO<sub>5</sub> were easily obtained.

41 **1. Introduction**

42 Spherical porous granules (SPGs) are promising for many applications, *e.g.*, heterogeneous  
43 catalysts, catalyst supports, drug delivery carriers, healing of defective bones and so on [1-8]. A  
44 variety of processes have been developed to form SPGs; they are mostly liquid-based processes,  
45 particularly spray drying [1,2], suspension hardening [3,4], drop-in-oil [5], sol-gel granulation [6]  
46 and freeze-granulation [2,7]. Solid-based processes are rarely realized for the SPG production,  
47 except the mechanical granulation method with a rotating fluidized bed [8]. Recently, we have  
48 reported a new solid-based process to synthesize SPGs by a one-step heat-treatment of the  
49 MgCO<sub>3</sub>(basic)-α-Fe<sub>2</sub>O<sub>3</sub>-Nb<sub>2</sub>O<sub>5</sub> mixed powder. Pseudobrookite-type MgFeNbO<sub>5</sub> SPGs with 3-D

1  
2  
3 network structure, typically 50-100  $\mu\text{m}$  in diameter, were successfully obtained (Fig. 1) [9].

4 This pyrolytic reactive granulation (PRG) process is really simple, consisting only of typical  
5 ceramic processes, *viz.*, wet-ball milling of starting powders, vacuum drying, granulation via sieving  
6 through a screen mesh, and a simple heat treatment (without pressing). Nevertheless, this new  
7 mechanical and solid-based process yields porous granules with relatively high sphericity [9]. This  
8 PRG process is similar to the pyrolytic reactive sintering process used to obtain bulk porous  
9 ceramics [10-12]; emitted  $\text{CO}_2$  or  $\text{H}_2\text{O}$  gas in starting carbonates, hydroxides etc. formed a uniformly  
10 open porous 3-D network structure with pore diameter of  $\sim 1 \mu\text{m}$ . The final diameter (typically  
11 50-100  $\mu\text{m}$ ) of SPGs by the pyrolytic reactive granulation is probably governed by the opening size  
12 of sieving mesh ( $< 150 \mu\text{m}$ ) used in the powder process before the heating.

17

18 Previously [9], microstructure development during heating was investigated with *ex situ* (i.e.,  
19 ordinary) SEM observation for the samples after heating at intermediate temperatures. With an *ex*  
20 *situ* SEM observation, dynamic microstructure development cannot be followed. *In situ*  
21 high-temperature (HT) microscopy is effective to dynamically pursue the microstructure  
22 development during the heating. Depending on the sample size/shape and the required resolution,  
23 optical microscopy (OM), scanning electron microscopy (SEM) [13-15], transmission electron  
24 microscopy (TEM) [16-18] and scanning probe microscopy (SPM) [19] have been combined with  
25 HT observation. Recently, confocal laser-scanning microscopy (CLSM), an advanced type of optical  
26 microscopy, can be utilized for the HT observation, where an infrared image furnace enables the HT  
27 observation up to as high as 1800°C in air. The HT-CLSM is increasingly being used in metallurgy  
28 and ceramic fields [20-23].

34  
35

36 Here the primary purpose is to clarify the microstructural development during the heating of  
37 SPGs by using the HT-CLSM. The secondary purpose, based on the outcome from the HT-CLSM, is  
38 to develop a facile size-control method for SPGs.

## 42 **2. Experimental**

### 43 *2.1. Materials*

44 As before [9], commercially available  $\text{MgCO}_3$  (basic) (hydromagnesite,  
45  $\text{Mg}_5(\text{CO}_3)_4(\text{OH})_2 \cdot 4\text{H}_2\text{O}$ , 99.9%, Kojundo Chemical Laboratory),  $\alpha\text{-Fe}_2\text{O}_3$  and  $\text{Nb}_2\text{O}_5$  (99.9% each,  
46 Wako Pure Chemical Ind.) powders were used as the starting materials. Prior to the weighing,  
47 TG-DTA analysis (up to 1000 °C) on the  $\text{MgCO}_3$  (basic) powder was conducted to determine the  
48 weight-loss during the heating. The  $\text{MgCO}_3$  (basic),  $\alpha\text{-Fe}_2\text{O}_3$  and  $\text{Nb}_2\text{O}_5$  powders (Mg:Fe:Nb = 1:1:1  
49 in mole fraction) were wet-ball milled for 24 h in ethanol with  $\text{ZrO}_2$  balls, vacuum dried and sieved  
50 through 100 mesh screen ( $< 150 \mu\text{m}$ ).

A confocal laser scanning microscope using a 408 nm violet laser (VL2000DX, Lasertec, Japan) equipped with a high-temperature *in-situ* observation system is used with an infrared image furnace (SVF17SP, Yonekura, Japan, as shown in Fig. S1). The  $\text{Mg}_5(\text{CO}_3)_4(\text{OH})_2 \cdot 4\text{H}_2\text{O}$ – $\text{Fe}_2\text{O}_3$ – $\text{Nb}_2\text{O}_5$  mixed powder in a small alumina crucible (6.5 mm $\phi$ ) was observed up to 1400°C under flowing air with a ramp rate of 100°C/min for R.T.-800°C and 20°C/min for 800-1400°C.

### 2.3. Synthesis and size control of spherical porous granules

The  $\text{Mg}_5(\text{CO}_3)_4(\text{OH})_2 \cdot 4\text{H}_2\text{O}$ – $\text{Fe}_2\text{O}_3$ – $\text{Nb}_2\text{O}_5$  mixed powder in an alumina crucible was heated to 1300°C in a box furnace (ramp rate: 5°C/min) with 30 min holding at the maximum temperature. The temperature of the furnace was verified using TempCHEK pellets (Orton, USA). The constituent phases of SPGs were analyzed by X-ray diffraction (XRD, Cu-K $\alpha$ , 40 kV and 40 mA, Multiflex, Rigaku, Japan). Quantitative composition analysis of the Pt-coated SPGs was carried out with SEM-EDS (SU-70, Hitachi / INCA System, Oxford) at the acceleration voltage of 15 kV. Based on the preliminary result of HT-CLSM observation, we decided to use multiple screens for the classification of spherical porous granules (Fig. 2); it is an old-fashioned way, but is really cost effective and compatible with industrial powder processes. Using 3 meshes with different openings (150, 100 and 75  $\mu\text{m}$ ), SPGs were classified with manual vibration for ~5 min. The classified SPGs were observed by SEM, and their diameter values (500 granules for each sample) were determined by image analysis using Image-J software.

## 3. Results

### 3.1. *In situ* high-temperature observation

Figure 3 shows the microstructure development of SPGs observed by HT-CLSM. Percentages in photos show the diameter change of a selected granule during the heating. Shrinkage of the granules is clearly observed from 120 to 900°C, which is mainly attributed to the pyrolysis of  $\text{Mg}_5(\text{CO}_3)_4(\text{OH})_2 \cdot 4\text{H}_2\text{O}$ . At around 1100-1300°C, the sphericity improves caused by the reactions and rearrangements of the constituent grains, in particular for larger granules. The  $\text{MgFeNbO}_5$  porous granules retained their spherical shape up to ~1350°C (with gradual densification), but began to be consolidated at ~1400°C due to local eutectic liquid phase formation. The *in situ* high-temperature observation clearly demonstrates the size change during the pyrolytic reactive granulation, which suggests that the classification (unification of the size) of rigid  $\text{MgFeNbO}_5$  SPGs should be much easier after heating than that of soft agglomerates before heating.

### 3.2. Synthesis and size control of SPGs

Figure 4 shows an XRD pattern of SPGs, showing almost single-phase pseudobrookite-type  $\text{MgFeNbO}_5$  with a trace of spinel phase, as seen in the previous work [9]. Some isolated intermediate,

1  
2 but rather stable, spinel grains co-existed in the porous structure. Figure 5 shows a result of  
3 SEM-EDS wide-area analysis of an MgFeNbO<sub>5</sub> SPG. Semi-quantitative analysis using INCA  
4 software indicated that the SPG was composed of 11.6 at.% Mg, 11.9 at.% Fe, 12.1 at.% Nb and  
5 64.5 at.% O, which are close to the ideal composition of 12.5 at.% of each metal and 62.5 at.% of  
6 oxygen. Note that the estimated error by Pt coating is less than 1 at.% in this study. The uniformly  
7 open-porous structure is composed of somewhat elongated grains with irregular shapes as commonly  
8 observed for pseudobrookite-type ceramics.  
9

10  
11 Figure 6 shows SEM micrographs and particle-size distributions for SPGs after multiscreen  
12 classification/sampling: (a) between 100 and 150 μm openings (sample A), and (b) between 75 and  
13 100 μm openings (sample B). Due to the mild manual vibration/sieving, some finer granules still  
14 remained for both samples in Fig. 6. However, nearly monodispersed granules can be easily obtained  
15 by such an "old-fashioned" but versatile method. Note that some granules with ellipsoid-like or  
16 irregular morphologies passed through the mesh possessed somewhat larger sphere-equivalent  
17 diameters. It is also noteworthy that, as is seen in HT-CLSM, larger granules tend to have better  
18 sphericity, which is confirmed by the aspect ratio analysis.  
19

20 The BET surface area of samples A and B were 0.52 m<sup>2</sup>/g and 0.57 m<sup>2</sup>/g, respectively. These  
21 values are similar to those of bulk UPC-3D (uniformly porous ceramics with 3-D network structure)  
22 as before [10,11].  
23  
24  
25

## 26 27 28 29 30 31 32 33 **4. Discussion**

### 34 *4.1. Microstructure development of SPGs*

35 For the *ex situ* SEM observation [9], sample preparation steps (*e.g.* fixation of granules on  
36 carbon tape using a spatula) somewhat affected the macroscopic sample shapes, particularly for the  
37 soft granules. After the pyrolysis of Mg<sub>5</sub>(CO<sub>3</sub>)<sub>4</sub>(OH)<sub>2</sub>•4H<sub>2</sub>O phase (*i.e.*, MgO nanoparticle  
38 formation) at intermediate temperatures, the mechanical strength of the granules seems be weak, and  
39 hence, the macroscopic sample shapes can be easily collapsed. A major advantage of the *in situ*  
40 method, as here, is that it avoids a deformation of the shapes of granules during the preparation  
41 necessary in the *ex-situ* method [9]. Another advantage is to avoid the secondly atmosphere effect of  
42 H<sub>2</sub>O and CO<sub>2</sub> in air reacting with *e.g.* MgO nanoparticles,  
43  
44  
45  
46  
47

48 The diameter of a selected granule (Fig. 3) decreased by 50-60% of the initial size. This  
49 shrinkage for SPG was more extensive than that for bulk green samples with pre-pressing. Without  
50 macroscopic liquid phase formation, each granule can unrestrictedly deform. Based on the *in situ*  
51 HT-XRD [9] and the HT-CLSM analyses in this study, the microstructure development of SPGs  
52 during the heating is schematically illustrated in Fig. 7. Even before the heating, the mixed powder  
53 was composed of "spherical-like" granules with somewhat large size distribution. During the heating,  
54 pyrolysis of Mg<sub>5</sub>(CO<sub>3</sub>)<sub>4</sub>(OH)<sub>2</sub>•4H<sub>2</sub>O occurred, and thus, the granules were shrunk. Formation of  
55  
56  
57

65

intermediate binary oxides ( $\text{MgNb}_2\text{O}_6$  (ss),  $\text{MgFe}_2\text{O}_4$  (ss) and  $\text{FeNbO}_4$  (ss)) and ternary oxide ( $\text{MgFeNbO}_5$ ) helped to rearrange the grain networks, and thereby improved the macroscopic sphericity. Up to  $1350^\circ\text{C}$ , without macroscopic liquid phase formation, the porous granules retained their spherical shapes.

#### 4.2. Size control of SPGs

As is stated in Section 3.1, the classification (unification of the size) of rigid  $\text{MgFeNbO}_5$  SPGs with 3-D network structure after the heating should be much easier than that of soft agglomerates of the mixed powder before the heating. It is demonstrated (Fig. 6) that some SPGs by furnace heating (not by the *in situ* observation) had the diameter of  $\sim 150\ \mu\text{m}$ , which implies the size shrinkage under the slower heating rate became milder. Formation of the 3-D network structure may result in such mild shrinkage (or even expansion) during the heating [24].

#### 4.3. Potential applications of SPGs

Although the base compound,  $\text{MgTi}_2\text{O}_5$ , does not show high catalytic activity (except photocatalytic activity), these ternary compounds,  $\text{MgFeNbO}_5$  and  $\text{MgFeTaO}_5$  (as originally reported by Bayer [25]) may be useful as redox catalysts. The specific surface area of the SPGs is relatively small, but the spherical granular shape with open pores should be favorable for heterogeneous catalysis. Moreover,  $\text{MgFeNbO}_5$  SPGs might be applied for biomaterials because  $\text{MgFeNbO}_5$  is composed only of biocompatible elements.

### 5. Conclusions

We have attempted in this study (1) to clarify the microstructural development during the heating of SPGs by using the HT-CLSM, and (2) to develop a facile size-control method of SPGs. Thus,

(1) The size and morphological change of SPGs during heating was successfully observed by *in situ* HT-CLSM. At around  $1100\text{--}1300^\circ\text{C}$ , the sphericity seems to be quite improved caused by the reactions and rearrangements of the constituent grains, in particular for larger granules.

(2) The classification via multiscreen sieving for the rigid  $\text{MgFeNbO}_5$  SPGs after heating was effective for the size-unification. This very simple, old-fashioned technique enabled nearly monodispersed SPGs.

11  
12 **Fig. 2** Multiple screens for the classification of spherical porous granules.  
13

14  
15 **Fig. 3** Microstructure development of spherical porous granules (SPGs) observed by *in situ*  
16 high-temperature confocal laser-scanning microscopy (HT-CLSM). Percentages in photos  
17 show the diameter change of a selected granule during the heating.  
18  
19  
20

21  
22 **Fig. 4** XRD pattern of spherical porous granules, showing almost single-phase  $MgFeNbO_5$  with  
23 trace spinel phase.  
24

25  
26 **Fig. 5** SEM-EDS wide-area analysis of a  $MgFeNbO_5$  SPG, showing 11.6 at.% Mg, 11.9 at.% Fe,  
27 12.1 at.% Nb and 64.5 at.% O, which are close to the ideal composition of  $MgFeNbO_5$ :  
28 12.5 at % of each metal and 62.5 at % of oxygen.  
29  
30  
31

32  
33 **Fig. 6** SEM micrographs, particle-size distributions and aspect ratio for spherical porous  
34 granules (SPGs) after multiscreen classification: (a) sampling from the screens between  
35 100 and 150  $\mu m$  openings, and (b) sampling from the screens between 75 and 100  $\mu m$   
36 openings.  
37
