#### Abstract

Background and aim: Hypertension as a risk factor for cardiovascular disease has growing prevalence. An increase in body weight is typically followed by an increase in blood pressure. This study aimed to investigate the association of general and central obesity with hypertension in Indonesian women using WHO and Indonesian classification systems.

Methods: Cross-sectional study of Indonesian women aged 18 years or and more (313,714 participants), using national level Indonesia National Basic Health Research (2013).

Results: The prevalence of hypertension in Indonesian women in this study was $32.8 \%$. Based on logistic regression analysis, hypertension was significantly associated with residential area, educational attainment, self-reported smoking status, cardiovascular disease, chronic kidney disease, diabetes mellitus, body mass index and waist circumference. Furthermore, the odds of having hypertension for general and central obesity according to WHO classification were adjusted odds ration (aOR) 2.61, $95 \% \mathrm{Cl} 2.52-2.70$ and aOR 1.50, $95 \% \mathrm{CI} 1.46-1.53$. By Indonesian classification were aOR 2.21, $95 \% \mathrm{Cl} 2.16-2.26$ and aOR 1.48, $95 \% \mathrm{CI} 1.45-1.51$.

Conclusion: By using International WHO and standard Indonesia classification systems, general and central obesity were associated with hypertension in Indonesia women. Thus, not only general obesity but also central obesity should be used to assess obesity in Indonesian women.

Keywords: hypertension, general obesity, central obesity, Indonesian women.

[^0]
## 1. Introduction

Hypertension, known as a silent killer, contributes to cardiovascular disease, stroke and premature mortality (1). In Indonesia, cardiovascular disease is the number one cause of death (2). Both general and central obesity can be used to identify hypertension. (3,4). Furthermore, increase in arterial pressure was shown to be associated with weight gain and it is estimated that 60-70\% of adults hypertension is related to adiposity (5). Thus, not only body mass index (BMI) but also waist circumference (WC) should be considered when assessing hypertension risk (6).

In Indonesia, obesity has shown an increasing trend from year to year, with women having a higher prevalence of obesity (7). Moreover, women have greater population attributable risk levels related to excess weight for hypertension compared to men (8).

The use of lower BMI cut-offs for the Indo-Asian population may be required to give optimal identification of people who are at risk of getting hypertension (9). People in Asia and Europe have different associations between body fat level, BMI score, and health risks (10). Thus it is important to consider the differences in BMI classification system to ensure a valid and reliable system to assess obesity (11). To the best of author's knowledge, there are no other studies using recent and national scale data to examine the association of both general and central obesity with hypertension in Indonesian people.

## 2. Methods

### 2.1. Study population

The subjects were Indonesian women aged 18 or above. The subjects were selected from Indonesia Basic Health Research (RISKESDAS) 2013, a national scale research that collected basic health data and indicators. Ethics for the survey was accepted by the committee of the National Institute of Health and Research Development, Ministry of Health, Republic of Indonesia. Pregnant subjects, and those with missing data on BMI, WC, and blood pressure, were excluded from the study. Hypertension was defined if one of the following status applied: systolic blood pressure (SBP) $\geq 140 \mathrm{mmHg}$; diastolic blood pressure (DBP) $\geq 90$ mmHg ; or presently taking medicine for hypertension. This study used the mean of two times blood pressure measurements.

### 2.2. General and central obesity categories

The study used both World Health Organization and Indonesian classification for general and central obesity. General obesity was determined by BMI in $\mathrm{kg} / \mathrm{m}^{2}$. WHO classification for BMI are underweight $=\mathrm{BMI}<18.5 \mathrm{~kg} / \mathrm{m}^{2}$; normal $=\mathrm{BMI} 18.5-24.99 \mathrm{~kg} / \mathrm{m}^{2}$; overweight $=$ BMI $25-29.99 \mathrm{~kg} / \mathrm{m}^{2}$ and obese $=\mathrm{BMI} \geq 30 \mathrm{~kg} / \mathrm{m}^{2}$ (10). The Indonesian classification for BMI are underweight $=\mathrm{BMI}<18.5 \mathrm{~kg} / \mathrm{m}^{2}$; normal $=\mathrm{BMI} 18.5-24.99 \mathrm{~kg} / \mathrm{m}^{2}$; overweight $=$ BMI 25-26.99 $\mathrm{kg} / \mathrm{m}^{2}$; and obese $=\mathrm{BMI} \geq 27 \mathrm{~kg} / \mathrm{m}^{2}(7)$.

Central obesity was assessed by measuring waist circumference. In the study, the participants waist circumference size was measured at a central point between the lower ribs and iliac crest (12). The cut-offs for central obesity in WHO and Indonesian classifications are $\geq 88 \mathrm{~cm}$ and $\geq 80 \mathrm{~cm}$, respectively $(7,13)$.

### 2.3. Covariates

Responses to the questions from the RISKESDAS questionnaire were used to obtain the covariates. Data for age was obtained from the household member question section. Age was grouped into young age $=18-39$ years old, middle age $=40-54$ years old, and old age $=\geq$ 55 years old. Residential area was classified as rural or urban areas. Marital status was classified as single or married. Educational attainment was categorized into three groups with high school as cut-off points (less than high school, high school, more than high school). The question about chronic kidney disease was phrased as "Have you ever been diagnosed you with chronic kidney disease (minimum of three consecutive months) by a doctor?" with yes and no responses. The question about diabetes mellitus was phrased as "Have you ever been diagnosed with diabetes mellitus by a doctor?" with yes and no responses. The question about hyperthyroid was phrased as "Have you ever been diagnosed with hyperthyroid by a doctor?" with yes and no responses. Cardiovascular disease data was obtained by a response to the question "Have you ever been diagnosed with heart failure or coronary heart disease by a doctor?" with yes and no responses. Self-reported smoking status was ascertained by the response from the tobacco consumption question and participants were grouped based on smoking history as: never, former or current smokers. Physical activity was obtained from the question: "Do you usually have continuous moderate physical activity for at least for 10 minutes for each activity?" and participants were classified based on WHO Global Physical

Activity Questionnaire analysis guide as less active if total physical activity time is 0 to $<150$ minutes and active, for 150 or more minutes/week (13).

### 2.4. Statistical analysis

Continuous variables were described as mean (M) $\pm$ standard deviation (SD) while categorical variables as frequencies and percentages. The difference between hypertensive and normotensive groups in this study was compared by chi-squared test for categorical variables and paired t-test for continuous variables. Spearman correlation analysis was conducted to check the correlation of each research variable.

Logistic regression analysis was done to measure the crude and adjusted odds ratio along with $95 \%$ confidence interval. Variables showing significant association with hypertension by alpha level <0.05 were selected as covariates in the adjusted logistic regression analysis. Hypertension was examined as outcome variable along with BMI and central obesity as predictor variables adjusted for age, residential area, educational attainment, chronic kidney disease, self-reported smoking status, cardiovascular disease, diabetes mellitus and hyperthyroid. All of the analyses were conducted in SPSS 22.0 (SPSS Inc., Chicago, IL).

## 3. Results

A total of 346,799 subjects aged $\geq 18$ years old were examined. From those examined, 33,085 participants were excluded with detail of 7464 women in pregnancy; 13,777 due to missing data on blood pressure measurement; 11,844 because of missing data on BMI and WC. The final analytical sample included 313,714 participants.

Table 1 presents the prevalence of hypertension in Indonesian women based on their characteristics. The overall rate of hypertension was $32.8 \%$ and it is significantly associated with residential area, educational attainment, cardiovascular disease, chronic kidney disease, self-reported smoking status, diabetes mellitus, hyperthyroid, BMI, and WC. Those people living in urban areas, married, and former smokers, tend to have higher hypertension prevalence. People with diabetes mellitus, hyperthyroid, cardiovascular or chronic kidney disease have higher hypertension prevalence compared to those without the disease. The comparison between hypertensive and normotensive groups was listed in Table 2. There were significant differences for all characteristics inspected between normotensive and
hypertensive groups. The hypertensive group was significantly older in age; higher in weight, BMI, WC, SBP, and DBP, compared to normotensive group.

In logistic regression model utilizing Indonesia classification, all covariates except for living in rural area and former smokers were significantly associated with hypertension. The odds for general obese people to get hypertension were about 2.21 times higher compared to people with normal BMI and the odds for central obese people were 1.48 times higher as compared to people without central obesity after adjusting for the covariates.

In WHO classification, all covariates except for former smokers were significantly associated with hypertension. The odds for general obese people to get hypertension were about 2.61 times higher compared to people with normal BMI and the odds for central obese people were 1.50 times higher compared to people without central obesity after adjusting for the covariates.

## 4. Discussion

Hypertension in Indonesia is a growing problem with dramatic increases of raised blood pressure in adults from 5\% in 1998 to $32 \%$ in 2008 (14). In this study, the rate of hypertension in Indonesian women using established Indonesia classification was $32.8 \%$. Compared to men, the prevalence of both obesity and hypertension in Indonesia is higher in women (15). The higher rate of women with hypertension in Indonesia is interesting as other south east Asian countries have higher prevalence in men (14). In general, the risk factors contributing to the high prevalence of hypertension in Indonesia may be due to an aging population, genetic factors, less physical activity, and an inappropriate diet that may lead to the increasing prevalence of obesity $(15,16)$.

Hypertension is significantly associated with residential area, educational attainment, cardiovascular disease, chronic kidney disease, smoking, diabetes mellitus, hyperthyroid, BMI, and WC. People living in urban areas, married people, and former smokers, tend to have higher hypertension prevalence. People with diabetes mellitus, hyperthyroid, cardiovascular or chronic kidney disease have higher hypertension prevalence compared to those without the above diseases.

Hypertension prevalence is increasing respective to weight gain. In this study, 48.8\% of obese people have hypertension by using Indonesian cut-off value, and $54.1 \%$ of obese people have hypertension by using WHO cut-off value. The results are similar to previous findings in which higher BMI resulted in higher prevalence of hypertension (16-18). Several mechanisms support the effect of weight gain on increasing blood pressure. Both total body fat described as BMI and abdominal fat described as WC affect blood pressure by several mechanisms including insulin resistance, which results in greater fatty acid release attributable to hypertension and the other mechanism, adipokines release such as leptin by increasing sympathetic outflow $(5,19)$.

These physiological mechanisms support the major finding in this study that, after adjusting for all covariates, general and central obesity were associated with hypertension in Indonesian women according to established Indonesian or WHO classifications for obesity. Indonesian women with general obesity have a twofold excess risk to developing hypertension compared to non-obese members of the population. The previous finding found that the increasing trend of being overweight or obese among women caused by higher
socioeconomic status and residence in urban areas has a strong connection with the risk to have high blood pressure (20).

In detail, based on Indonesia classification, the odds for generally obese people to develop hypertension were 2.21 times higher compared to people with normal BMI and the odds for abdominally obese people were 1.48 times higher, as compared to people without abdominal obesity after adjusting for the covariates. Using WHO classification, the odds for generally obese people to get hypertension were about 2.61 times higher compared to people with normal BMI and the odds for abdominally obese people were 1.50 times higher compared to people without abdominal obesity after adjusting for the covariates.

The result in this study showed that having abdominal obesity will also give a risk to get hypertension. The association and odds of hypertension is consistent with several previous studies (21-23), one previous study stated in detail that for every additional 1 cm in waist circumference, the odds for hypertension is 1.04 times higher (24). Therefore, both BMI and waist circumference should be examined to assess hypertension in Indonesian women. This is consistent with the a previous study that suggests using not only BMI but also WC as significant predictors of hypertension in the population (25).

Both general and central obesity assessment are important to improve the evaluation of potential health risks and to provide accurate prognosis by estimating fat distributions. Additionally, previous research found that each fat depots such as lower body, upper body and visceral have unique characteristics related to the metabolism of fatty acid (26). For people at risk who tend to store their excess weight abdominally, determination of waist circumference will help to improve the treatment (27). Therefore, in assessing patients with health risks associated with obesity, measuring waist circumference as a complement of simple BMI measurement is necessary.

The odds of having hypertension and the rate of general as well as central obesity using the Indonesia classification differed from WHO classification. In general, Asian people are likely to have a higher percentage of total body fat and central adiposity compared to Caucasian people $(10,27)$. Considering this difference, the International diabetes federation suggested a threshold for waist circumference is more than or equivalent to 80 cm for Asian women (28). Another research conducted on a population in Pakistan found out that a quarter of the study population was classified as overweight or obese using the Asian cut-offs
(9). The use of a lower BMI classification may provide reliable estimation and optimal identification of obesity-related disease risks in Asian populations (29).

The large sample size equipped with various confounders and nationally representative data increased the validity of this study. Nevertheless, one limitation of this study is it is crosssectional study that gives only a one-time measurement for classifying the BMI and WC score from the participants. Therefore, it is difficult to state a direct causal inference. Further longitudinal studies are needed to asses the effect size of general and central obesity on hypertension.
